Foreword

"End of Urology," so spoke the late Richard Williams, my good friend and colleague, when as residents we witnessed a newly arrived faculty* at the University of Minnesota begin to do with tubes and wires through small holes what we could do so much more adeptly and expeditiously through our macho incisions. "A flash in the pan," so commented the renowned Victor Politano at a meeting in the mid 1980s where Endourology was being presented. "Small incisions are for small surgeons," – the words of surgeon advocates of the massive incision because exposure was king and, after all, incisions healed from "side to side."

"Endourology" was the branding brainchild of Elwin Fraley, Arthur Smith, and Paul Lange. Most felt that the Minnesota cold had finally gone beyond their defenses to create a "brain freeze" of monumental proportions. Fast forward 30 years and, today, Endourology has become Urology. From the urethral meatus to the uppermost renal calyx, the entire urogenital tract is endoscopically accessible and radiologically visualizable. From the smallest to the most complicated open procedure, urologists of talent, innovation, and persistence have supplanted standard incisional access with the endoscope or image-guided therapy. This is the age of surgical nihilism and Endourology has been at the forefront from day one.

If you are reading this foreword, then you hold in your hands a book (or CD) that contains every aspect of Urology and how it is impacted by a minimally invasive approach, be it percutaneous, ureteroscopic, laparoscopic, robotic, or image-guided. The authors are a Who's Who of experts in endourology on a global scale. The content ranges from basic to futuristic Endourology. The latest advances in supine percutaneous stone removal, endoscopic nephrostomy, laparoendoscopic single site surgery as well as natural orifice transluminal endoscopic surgery are clearly detailed and illustrated both in still photographs and often by instructional video demonstrations.

A wise mentor* once informed me that "You are only as good as tomorrow." That single daunting sentence should haunt each of us as we arise every morning to provide relief to those who suffer. To that end, we must seek methods to relieve suffering without causing it, to heal without harming, to cure without creating another, sometimes worse, malady. Endourology empowers every urologic surgeon with the knowledge and tools to provide all individuals seeking our care with a kinder gentler solution to their problem…one that neither disfigures nor maims in the name of treatment. In the words of Sir William Osler "Diseases that harm, require treatments that harm less." A century later, his dictum has become commonplace practice for the endourologist.

My heartfelt congratulations go out to Drs Smith, Badlani, Kavoussi, and Preminger – friends all – to me, to you, and to your patients. So read *Smith's Textbook of Endourology* well, apply its principles earnestly, and if opportunity presents, seek to innovate and improve. The text is not an end in and of itself, rather it is another paver in the surgical journey in which each of us plays a role – using techniques born of today's technology to ever reduce the burden of the "surgical" cure.

Ralph V. Clayman

Ralph V. Clayman, MD

University of California – Irvine
Dean – School of Medicine
Professor of Urology

*(Arthur D. Smith)

Preface

In 1978 the concept of Endourology was launched. It was defined as closed controlled manipulation within the urinary tract. The word "closed" was used to indicate either a minimal incision or no incision at all and the "control" was achieved either endoscopically or by non-invasive imaging. Until then, residents had been taught that the only way to get good exposure was through a large incision and now the ultimate goal is good exposure with no incision at all. It is achieved with a combination of endoscopy and all the new modalities of imaging. Now there are relatively few accepted open urological surgical procedures and this has had the gratifying result of a dramatic decrease of the morbidity in our patients recuperating after treatment. Because the field has expanded exponentially over the past three decades, the need has arisen for a new updated edition of this textbook.

From the outset, it has been policy of Endourologists to embrace, and evaluate fairly, all new tools and equipment. Consequently we have always been at the cutting edge of new technology. As technology has evolved, courses have been organized, to train not only residents and fellows, but also the practicing urologist, so that their learning curve has been accelerated enabling them to practice endourologic techniques comfortably and with the required expertise. The number of stone cases treated by open surgery today is minimal. Similarly open nephrectomy has almost exclusively been replaced by laparoscopic, robotic or percutaneous ablative techniques.

In this era of fewer working hours for residents, the amount of time that the residents spend in the operating room has decreased dramatically, and the necessary skills have to be taught using a combination of additional educational modalities. In addition to books and journals, there are an abundance of videos on surgical techniques, animal laboratories, teaching models and virtual reality simulators. Fortunately endourologic techniques are uniquely suited to these modalities and the student can become quite adept before being instructed in the operation room. These learning tools have helped urologists all over the world to become competent endourologists.

This 3rd edition has been completely re-written as the field has expanded to incorporate so many applications. The contributors to each chapter are either the innovators of the procedure they describe or alternatively have had vast experience with that technology. Wherever possible we have included videos to enhance the description of the various techniques and the readers will have the opportunity to watch experts doing the procedures. These videos are on portable computer discs which can be seen shortly before any intended endourologic operation as a "re-fresher."

The "Textbook" consists of 2 volumes – the 1st one on stones in the upper tract and the 2nd on laparoscopic and robotic surgery, image guided diagnostics and therapeutics and minimally invasive therapy of the lower urinary tract. The 1st volume has 5 parts:

Section 1 discusses basic principles of the care of instruments, how to protect oneself from radiation exposure, video imaging and documentation which has become so important in the area of electronic medical records. As gram negative septicemia is still prevalent in the management of stone patient's , antibiotic usage in the prevention of sepsis is included in the section. There is a chapter on anti-coagulant therapy which is so prevalent today in patients with coronary artery stents.

Section 2 is devoted to percutaneous renal surgery, from pre-operative evaluation to access, stone removal, other uses of the nephrostomy tract and the exit strategy and complications.

Section 3 discusses all the intricacies of ureteroscopy and Section 4 is devoted to shock-wave lithotripsy. We were cognizant that there is no single modality for treating stones and hence Section 5 describes the management of the patient with various stone related problems in a composite format.

As there is so much overlap between laparoscopic and robotic surgery we combined them in Section 6. At present, the dividing line between the techniques is primarily related to technical experience and availability of the robot together with financial considerations.

Section 7 which discusses image-guided diagnostics and therapeutics, is an important addition to this textbook on Endourology as it is an essential component of the armamentarium of the practicing urologist.

We are moving into an era of "no incisions", and if the procedures described in this section are not performed by urologists, they will be taken over by radiologists. This would result in the loss of continuity of care of our patients.

Finally, Section 8 discusses management of the lower urinary tract. Emphasis has been placed on many ambulatory procedures, as this is an escalating trend endorsed by medical insurance plans.

I would like to thank each of the contributors for the many hours they devoted to writing, illustrating and creating videos for their chapters.

Hopefully they will be as delighted with the results as the editors and publishers of this "Textbook." I am also deeply indebted to my co-editors who have reviewed edited and re-reviewed chapters countless times. I thank not only them but their families as well, for the time spent on the book could have been devoted to them.

The staff at Wiley-Blackwell have been highly efficient, professional and encouraging. When one deals with a large organization it is reassuring to know that as the book passes from one stage to the next and hence to separate departments there is "continuity of care" throughout the operation. They are a great team and we, the editors, appreciate all the help we received from them.

Finally I would like to thank my wife, Kay, who inspired me to edit this 3rd edition and has repeatedly helped me with this text and countless other projects throughout my academic career. If I am regarded as the "father" of Endourology, she is unquestionably the "mother" that helped nurture this field of urology.

Bristol Urological Institute
Southmead Hospital
Bristol, UK

Michael J. Kennelly MD FACS
Director, Charlotte Continence Center
McKay Department of Urology
Charlotte, NC, USA;
Associate Clinical Professor, University of North Carolina
Chapel Hill, NC, USA

Harold Kim MD
Assistant Professor of Anesthesiology
Hofstra North Shore–LIJ School of Medicine at Hofstra
University
Long Island Jewish Medical Center
New Hyde Park, NY, USA

Amy E. Krambeck MD
Mayo Clinic Department of Urology
Rochester, MN, USA

Cynthia Kuk BSc(Hons), MSc
Division of Urology
Mount Sinai Hospital
Department of Surgical Oncology, Urology
University Health Network
Toronto, Canada

Ali Rıza Kural MD
Professor of Urology
Department of Urology
School of Medicine
Istanbul Bilim University
Istanbul, Turkey

M. Pilar Laguna MD PhD FEBU
Professor of Urology
Department of Urology
AMC University Hospital
Amsterdam, The Netherlands

Sven Lahme MD
Associate Professor
Head of Department
Department of Urology
Siloah St. Trudpert Klinikum
Pforzheim, Germany

Jaime Landman MD
Professor of Urology and Radiology
Chairman, Department of Urology
University of California Irvine
Irvine, CA, USA

Michael S. Lasser MD
Urology Chief Resident
Brown University Medical School;
Rhode Island and Miriam Hospitals
Providence, RI, USA

Melissa Laudano BSc MD
Urology Resident
Weill Medical College of Cornell University
New York, NY, USA

Benjamin R. Lee MD FACS
Professor of Urology & Medicine (Oncology)
Robotics, Endourology and Laparoscopic Surgery
Tulane University School of Medicine
New Orleans, LA, USA

Fang Jann Lee MBBS (Singapore), MRCS (Ed), Mmed (Singapore)
Resident
Department of Urology
Singapore General Hospital
Singapore, Singapore

Jason Y. Lee MD FRCSC
Minimally Invasive Surgery and Education Fellow
Department of Urology
University of California – Irvine
Orange, CA, USA

Lucille Lee MD
Assistant Professor of Radiation Medicine
Hofstra North Shore-LIJ School of Medicine at Hofstra University
Department of Radiation Medicine
North Shore – Long Island Jewish Health System
New Hyde Park, NY, USA

Richard Lee MD MBA
Instructor
Weill Medical College of Cornell University
New York, NY, USA

Raymond J. Leveillee MD FRCS-G
Professor of Urology, Radiology & Biomedical Engineering
Division of Endourology, Laparoscopy, and Minimally Invasive Surgery
Department of Urology
University of Miami Miller School of Medicine
Miami, FL, USA

Evangelos Liatsikos MD PhD
Assistant Professor
Department of Urology
University of Patras
Patras, Greece

James E. Lingeman MD
Director of Research
Methodist Hospital Institute for Kidney Stone Disease;
Volunteer Clinical Professor
Indiana University School of Medicine
Department of Urology
Indianapolis, IN, USA

Michael E. Lipkin MD
Comprehensive Kidney Stone Center
Duke University Medical Center
Durham, NC, USA

Enrique Ian S. Lorenzo MD
Assistant Professor
Department of Urology
Urological Science Institute
Yonsei University
Seoul, Korea;
Department of Urology
Jose R. Reyes Memorial Medical Center
Manila, Philippines

Yair Lotan MD
Associate Professor of Urology
Department of Urology
University of Texas Southwestern Medical Center
Dallas, TX, USA

Michael K. Louie MD
Assistant Clinical Professor of Urology
Department of Urology
University of California
Irvine, CA, USA

Steven M. Lucas MD
Wayne State University
Detroit, MI, USA

John G. Mancini MD
Duke University Medical Center
Durham, NC, USA

Brian R. Matlaga MD MPH
Assistant Professor
The James Buchanan Brady Urological Institute
Urology Robotics Laboratory
The Johns Hopkins University School of Medicine
Baltimore, MA, USA

James A. McAteer
Department of Anatomy and Cell Biology
Indiana University School of Medicine
Indianapolis, IN, USA

Kurt A. McCammon MD FACS
Chairman, Department of Urology
Eastern Virginia Medical School
Norfolk, VA, USA

Elspeth M. McDougall MD FRCSC MHPE
Professor of Urology
Department of Urology
Director, Minimally Invasive Surgery Education Center
University of California
Irvine, CA, USA

Ben R. McHone MD
Urology Resident
Urologic Oncology Branch
National Cancer Institute
Bethesda, MD, USA

E. Fred McPhail MD
Resident
Mayo Clinic Department of Urology
Rochester, MN, USA

Salvatore Micali MD
Assistant Professor of Urology
Department of Urology
University of Modena & Reggio
Emilia, Italy

Nicole L. Miller MD
Assistant Professor of Urologic Surgery
Vanderbilt University School of Medicine
Vanderbilt University Medical Center
Nashville, TN, USA

Shashikant Mishra PhD
Consultant Urologist
Mulgibhai Patel Urological Hospital
Nadiad, Gujarat, India

Ali Moinzadeh MD
Director Robotic Surgery
Assistant Professor, Tufts University Medical School
Institute of Urology/Urologic Oncology
Lahey Clinic Medical Center
Burlington, MA, USA

Robert Moldwin MD
Associate Professor of Urology
Hofstra North Shore–LIJ School of Medicine at Hofstra University
Director, Pelvic Pain Treatment Center
The Smith Institute for Urology
North Shore - LIJ Healthcare System
New Hyde Park, NY, USA

Manoj Monga MD FACS
Professor of Surgery
Lerner College of Medicine at Case Western Reserve University;
Director, Stevan B. Streem Center for Endourology & Stone Disease
Glickman Urological & Kidney Institute
The Cleveland Clinic
Cleveland, OH, USA

Sylvia Montag DO
Urology Resident
The Smith Institute for Urology
North Shore – Long Island Jewish Health System
New Hyde Park, NY, USA

Courtenay K. Moore MD
Assistant Professor of Surgery
The Cleveland Clinic Lerner College of Medicine of Case Western Reserve University;
Staff, Center for Pelvic Health and Reconstructive Surgery;
Co-Fellowship Director, Female Pelvic Medicine and Reconstructive Surgery
Glickman Urological Institute at Cleveland Clinic
Cleveland, OH, USA

SECTION 1
Basic Principles

CHAPTER 1

Care and Sterilization of Instruments

Carol Olsen

The Arthur Smith Institute for Urology, North Shore – Long Island Jewish Health System, New Hyde Park, NY, USA

History of sterilization

Surgical instruments have been in use since prehistoric times. The effects of using instruments that were neither clean nor sterile were not a major concern in past eras. The methods for the care and sterilization of instruments have gone through an evolutionary change and have greatly improved over the last few centuries. It was not until the 19th century that a process for instrument sterilization was developed and recognized. During this time the focus on the need to sterilize instruments prior to a surgical procedure developed from the effects of postsurgical wound management and the need to eliminate the increased infections of these wounds. This recognition led to the evolution and development of the current standard practice of instrument sterilization.

Noted in the 19th century, surgeons performed operations in their street clothes, often times dirty street clothes, and reused instruments without a standard cleaning process. In 1864, Joseph Lister introduced the use of phenol, a carbolic acid, on inanimate objects and surfaces as well as human tissue, in the hospital wards and operating rooms, which resulted in a dramatic decrease in the incidence of wound infections. Carbolic acid was used in conjunction with other components to dress wounds in an antiseptic manner, which prevented bacteria from entering the wound. This led him to introduce other methods of asepsis, such as sterilization of surgical instruments by using an application of heat and carbolic acid, and the frequent cleaning of the surgeon's hands during an operation. After publication of these findings in the *The Lancet* in 1867, the "era of antiseptic surgery" was introduced into the field of medicine and surgery. By the year 1875 Lister's principles of antiseptic surgery were accepted worldwide [1, 2].

The steam autoclave was derived from a steam digester, currently known as a pressure cooker, invented by the physicist Denis Papin in the late 1600s. By 1879, Charles Chamberland, a colleague of Louis Pasteur, made improvements to Papin's invention and invented a porcelain dish with tiny holes that was able to filter microorganisms from liquid that was poured through this dish. This is known as the Chamberland filter or the Chamberland–Pasteur filter, and with his further research in 1884 the autoclave was invented. The use of pressurized steam sterilization of instruments with an autoclave was introduced by Ernst von Bergmann in 1886.

Ethylene oxide (ETO) was first used for sterilization in 1938 to preserve spices. In the 1950s, ETO was accepted by the medical device industry as a sterilant after a US army researcher investigated the microbicidal effect of ETO and published his findings [3].This method of sterilization has been used for heat-sensitive instruments, such as flexible scopes and lenses.

In the early 1900s, urologic instruments were sterilized in a formalin sterilizer and disinfected with a carbolic acid solution. The formalin sterilizer exposed instruments to heated formalin vapors for 2 h and remained in the sterilizer until use [4].

Since the late 1980s, other methods of sterilization have been developed that are less caustic to instruments, require shorter process time, are noncarcinogenic, and allow for sterile instrument availability. These methods have replaced some of the older sterilization methods.

Instrument processing

Any item, such as an instrument or medical device, that is intended to be reused in a sterile procedure, must be processed in a specific manner, beginning with cleaning

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

and ending with sterilization or high-level disinfection (HLD). In order for sterilization or HLD of an item to be effective, the following steps must occur in a proper and adequate manner; cleaning, decontamination, and manual drying. The method of sterilization or HLD will determine the necessary type of package or container the item will be placed in or, in some instances, the item may be placed in storage until reuse.

First the item should be categorized to determine which type of disinfection or sterilization method is recommended for processing. Earl H. Spaulding in 1968 categorized medical instruments and items used for patient care as critical, semicritical and noncritical, based on the degree of risk for infection with the processing and reuse of each item. These categories make up the Spaulding scheme or Spaulding classification, which is a recognized resource when describing the appropriate disinfection and sterilization process for medical instruments and devices [5, 6]. Critical items are instruments that will come in direct contact with sterile tissue, or enter the vascular system, or penetrate skin, and require sterilization by methods of steam, ETO, hydrogen peroxide gas plasma, or a liquid chemical sterilant such as peracetic acid. Semicritical items are instruments that will come in contact with mucous membranes and require sterilization or at a minimum HLD. Noncritical items are instruments or medical devices, such as a stethoscope or blood pressure cuff, that will come in contact with intact skin only and require intermediate-to-low level disinfection, such as an impregnated antimicrobial wipe [6–8].

Utilization of a reusable instrument or medical device is a major risk due to the potential introduction of pathogenic microorganisms which can lead to infection. Therefore, adequate cleaning is imperative to successfully eliminate the amount of bioburden or microbes present on an instrument. Cleaning and decontamination of any level item used in any type of healthcare facility is a mandatory requirement prior to reuse. Each facility must have a policy and procedure manual in place which identifies the process of cleaning or decontamination, followed by the process for disinfection or sterilization of these items.

Cleaning is the most important step in the process leading to sterilization or HLD and begins with physically removing microbes in preparation for the next step, which is decontamination [7]. There are different accepted methods for cleaning instruments prior to disinfection or sterilization, known as manual or automated with a washer/sterilizer, ultrasonic cleaner, or washer/decontaminator [9].

Prior to the cleaning process, any personnel must don protective personal equipment (PPE), including eye protection (goggles, mask with shield), mask, impervious apron, and gloves to avoid exposure to microorganisms and for personal safety protection [9].

The process of manual cleaning involves three components; detergent or enzymatic cleaner, a brush or sponge, and friction [10]. These components will ensure the removal of tissue and debris from an instrument. Manual cleaning of an item begins with immersion in a receptacle or deep sink filled with a detergent or enzymatic cleaner and warm water. Preparation of the detergent or enzymatic cleaner must follow the manufacturer's instructions to ensure the solution is the correct concentration. Many cleaners are designed with a premeasuring pump mechanism; personnel must make certain a full depression of the pump occurs to ensure appropriate solution concentration. A weak solution may fail to break down proteinaceous tissue or a strong solution may create sudsy bubbles which form air pockets and can prevent surface contact by the cleaner. To accurately fill the receptacle or sink with the correct amount of water, a fluid depth indicator or line should be placed for guidance of accuracy [10, 11]. An example is shown in Figure 1.1. A visible instruction guide should indicate the correct solution amount to be added to the correct measurement of water, e.g. 1 ounce of detergent to 1 gallon of water (Figure 1.2).

Prior to immersion, if the item has numerous parts, it must be disassembled, or a hinged instrument must be kept in the open, unlocked position. Gentle scrubbing of the item with a soft bristle brush or sponge will assist removal of bioburden and preservation of the instrument's functions and effectiveness [9]. To prevent aerosol formation from microorganisms, the item being cleaned should be kept immersed below the water level [7]. The next step in manual cleaning is to thoroughly rinse the item with cool water in a deep sink to allow for ample movement. Following the rinse process, sufficient drying time is needed before the item is prepared for sterilization or HLD.

Figure 1.1 Example of the fill line of a cleaning receptacle.

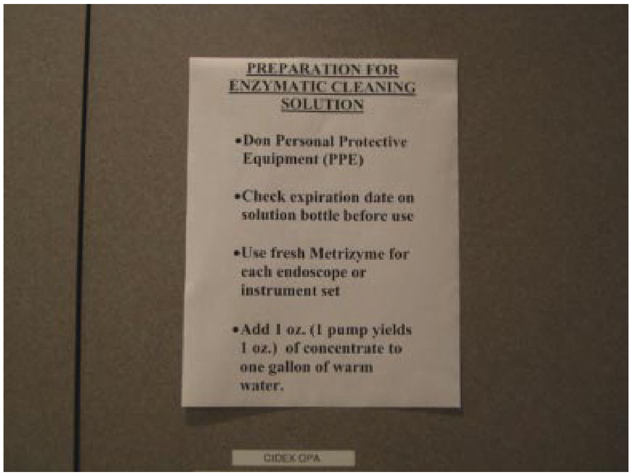

Figure 1.2 Visible instruction guide for preparing an enzymatic cleaner.

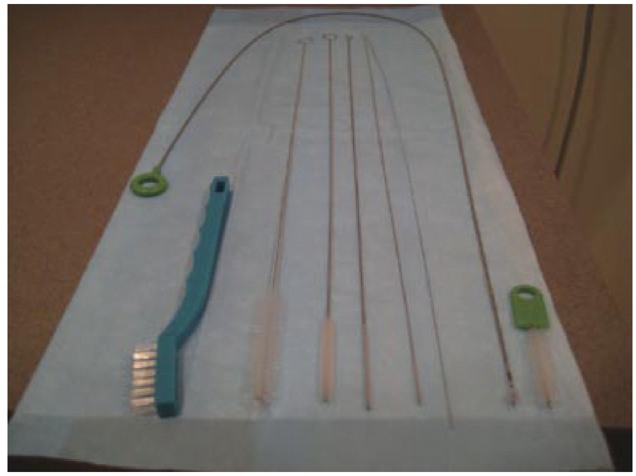

Figure 1.3 Examples of various cleaning brushes.

In urology, endoscopes, flexible or rigid, are frequently used, valuable diagnostic tools, which are reusable and require personnel to follow the guidelines for reprocessing to prevent an outbreak of infections due to improper cleaning. When indicated, a leak test should be performed on all flexible endoscopes prior to full immersion of the scope in the cleaning solution. External surfaces should be washed with a soft brush or sponge to remove any visible debris. Careful attention should focus on the lumens and working channels of all endoscopes. Lumens and working channels should be irrigated with a large syringe or a manufacturer designed irrigating device, first with detergent or enzymatic solution to help remove any residue, and then with a water rinse until it appears clear. Using an appropriate size flexible brush will allow for proper through-and-through cleaning of the lumens and working channels. Brushes are available in a variety of sizes and shapes to accommodate any manufactures' endoscopes, and proper selection is essential for prevention of damage to the endoscope (Figure 1.3). A newly prepared cleaning solution prior to each endoscope cleaning is most effective and helps prevent cross-contamination [10, 11].

A washer/sterilizer is designed to have several cycles, starting with a cold water prerinse, followed by a high temperature wash cycle with an alkaline low sudsing detergent, next a neutralizing cycle, followed by a final rinse, steam sterilization, and a drying cycle [8, 9]. An ultrasonic cleaner functions by a process of cavitation. Ultrasonic energy is passed through a water bath, creating microscopic bubbles that implode. The implosion process creates a suction action that pulls soil and foreign body matter away from instrument surfaces [8, 9]. The washer/decontaminator is a single or multichamber unit that cleans using an alkaline low sudsing detergent with a spray force action and heat for the drying cycle. The multichamber unit allows for multiple single tasks to be performed simultaneously, including a cool water rinse, prewash with an enzymatic cleaner, wash cycle with detergent, ultrasonic cleaning, pure hot water rinse, and high temperature dry time [8, 9].

Protection, handling, and maintenance of instruments

Protection, proper handling, and maintenance of instruments is vital in maintaining the efficacy of instruments, as well as keeping instrument replacement costs down [12]. During and immediately following a procedure, heavily soiled instruments should be immersed in warm water to prevent the onset of corrosion, pitting, and rusting [9, 12].

Proper handling of instruments is a crucial part of instrument maintenance generally. This is frequently overlooked with instruments handled in a careless manner. Any delicate instrument such as telescopes, flexible scopes, light cables, and fine instruments, such as microinstruments, must be handled in a specific manner. During a procedure these instruments should be kept in a separate location on the sterile field to avoid other instruments from being placed on top of them and causing potential damage. When transporting these delicate instruments to the soiled processing room, either they should be carried one at a time or in a specific container designed for instrument transport. Flexible scopes and light cables must not be over coiled while on the sterile field or during transport; this will help prevent the internal fiberoptics from being cracked.

After the cleaning process, instruments should be checked for their function and lubricated when recommended by the manufacturer with a water soluble lubricant [5]. Lubrication also helps prevent rusting and

maintains the function of any movable piece, such as a luer lock part.

Methods of sterilization

Sterilization can be achieved by several approved methods. These include using steam, ETO gas, peracetic acid, or hydrogen peroxide gas plasma. Each method has its advantages and disadvantages, along with specific indications for use. The manufacturer's guidelines for any instrument must be followed when selecting which method to use to ensure instrument viability and appropriate sterilization [13]. The healthcare setting will determine which method is suitable for the facility's operational workflow. Monitoring and documentation of the effectiveness of any sterilization method is a mandatory requirement and must be followed according to the facility's policy and procedure guidelines.

Steam sterilization

The process of steam sterilization occurs in a steam autoclave unit designed to produce boiling water equaling 121° and 132°C. The water along with pressure of 15 pounds per square inch (PSI) further produces steam to penetrate packaged or wrapped instruments, or instruments in sterilization containers, to kill any microorganisms present, including spores [14]. In order for steam sterilization to be successful, the following standards are required, exposure to direct pressurized steam, a specific temperature, and a specific length of time [5].

There are different methods of cycle performance with a steam autoclave. One is the gravity-displacement cycle, which removes air by the force of gravity from the top downward. Another is the prevacuum cycle, in which air is removed via a vacuum pump, also referred to as dynamic air removal [5]. The temperature and exposure time vary depending on the type of autoclave unit and the contents of the load.

The common cycle consists of 15 min of preheat, 15 min of pressurized steam, and 5–15 min of cooling [14]. The process of steam sterilization has been in existence for a long time and is recognized to be one of the most effective, safe, and economic sterilization techniques [15].

One major disadvantage of steam sterilization is the inability to sterilize heat-sensitive materials, such as plastic or some rubber materials. Some advantages are its short process time, allowing a quicker turnaround of packaged items, and its availability in various sizes, including one that allows it to be placed on a table top in an office setting, allowing it to be used in any healthcare setting.

Ethylene oxide

ETO has the ability to sterilize heat- and moisture-sensitive instruments and medical devices, such as ones made of plastic or rubber, flexible scopes, and other instruments with lenses. ETO sterilization is a lengthy process, lasting 12 h or longer, which decreases the availability of the instruments. The process must be carried out in an area with proper ventilation, vent-failure alarms, and a special sterilization chamber. ETO concentration must be carefully monitored in work areas to prevent potential injury to staff. Due to ETO's high flammability, it has been mixed with inert gases, such as carbon dioxide or a fluorinated hydrocarbon, to decrease the risk of fire. Freon 12 is a hydrocarbon which has been found to be a major contributor to the destruction of the earth's ozone layer. Since 1998 there has been a significant decrease in the use of ETO for sterilization, since other methods have been introduced [15]. Other disadvantages of ETO are its potential to cause harm to personnel if there is exposure, either acute or chronic. Irritation to the eyes or skin may occur from acute exposure. Chronic exposure may lead to hematologic changes, increased risk of spontaneous abortions, and various cancers [5].

Peracetic acid

In 1988 the introduction of sterilization with a peracetic acid compound provided a new method for medical and surgical instruments, including endoscopes and instruments with lumens. Peracetic acid is an oxidizing agent composed of acetic acid, hydrogen peroxide, and water, but has the disadvantage of being corrosive [16]. To allow for sterilization with peracetic acid, the STERIS Corporation in Mentor, Ohio, USA manufactured a sterilant of 35% peracetic acid and a noncorrosive chemical. This sterilant is packaged in a sealed, single-dose container, and is designed to be used in the manufacturer's table-top sterilizer. This system is to be utilized for "just-in-time" use, therefore it does not require instruments to be wrapped or packaged. The table-top system has covered tray inserts to accommodate various sizes of flexible endoscopes, rigid endoscopes, and other instruments. To circulate the sterilant and rinse water through the lumens and working channels of flexible and rigid endoscopes, specific connecting tubes have been designed to attach to the different styles of scopes.

This sterilization process requires filtered water of 50°C to dilute the sterilant to a 2% concentration, and the system is designed to empty the liquid concentrated sterilant via a drainage system that must be connected to the facility's waste management line. The final phase removes excess water by passing clean filtered air through the machine's chamber, including the tubing

connected to the lumens and working channels of the scopes. This table top unit is equipped with a computerized printout of the cycle's temperatures, length of time, and verification of completion status. Another feature of this unit is its ability to run a diagnostic cycle before daily use to ensure the unit has full functionality. An internal sensor will stop the unit and abort the procedure if an error in the process is detected [5, 16].

Gas plasma

The newest method of sterilization is the hydrogen peroxide gas plasma sterilization system, which has been available in the USA since 1993. This low temperature system allows for sterilization of instruments, especially heat-sensitive or delicate instruments, in a rapid time range of less than 1 h to 75 min, depending on the model [15].

The process of this technology is based on gas plasmas which have been referred to as the fourth state of matter (i.e. liquids, solids, gases, and gas plasmas) [5]. There are five phases of this process: (1) vacuum phase, (2) injection phase, (3) diffusion phase, (4) plasma phase, and (5) vent phase. Terminal sterilization occurs after these five phases have been completed.

The positive aspects of this system are there are no toxic fumes: no plumbing connections, no aeration time, and no ventilation system is required. The compact, free-standing system requires an area of minimal square footage and a 208 V electrical source [16].

Flash sterilization

Flash sterilization is a high-temperature, high-moisture process used to sterilize unwrapped instruments rapidly for just-in-time use. This method is most useful when an instrument becomes contaminated during a procedure and there is no sterile replacement. Other reasons for using this method may include low-volume inventory of specialty instruments that are needed for back–to-back procedures, or a surgeon brings a specialty instrument required for a procedure that is not available in the healthcare facility. During the last several years, the use of flash sterilization in healthcare facilities has become more transparent due to an increase in evidence of surgical site infections (SSIs) in patients who had a flashed item used or implanted during their procedure [5]. Although this is an approved method of sterilization for immediate use of a cleaned instrument or medical device, excluding heat- and moisture-sensitive items, such as flexible endoscopes, it has become a controversial method of use.

The process of flash sterilization will not be effective if the instrument or device has not been appropriately cleaned, decontaminated, and rinsed according to the manufacturer's instructions. The cleaned item to be flashed is placed in an open mesh pan or a specially designed rigid container with a lid that allows for rapid penetration of steam [5]. Once the sterilization cycle has been completed the sterile item is transported in a covered fashion to the point of use. Ineffective cleaning and sterilization can result in an SSI, increased length of hospital stay, increased hospital costs, and liability.

Multiple issues need to be considered when approving this method of sterilization in a healthcare facility. A most crucial issue is the location where the instrument will be cleaned prior to sterilization. It is ideal for the instrument to be processed in a designated soiled utility room that is designed with negative pressure and 10 air exchanges per hour [17]. If there is no designated soiled utility room within the operating environment, then the instrument should be brought to the Central Sterile Processing Department for adequate processing. Location of the flash sterilizer will determine which pan or container method will be utilized, such as an open pan versus a steam-penetrating container with a lid. With the recognition of flash sterilization, healthcare facilities are placing flash sterilizers in close proximity to specific operating or procedure rooms to assist in aseptic transport to the sterile field. Personnel retrieving and transporting the sterilized device must don heat-sensitive gloves to avoid potential risk of a burn. Once the item is accepted into the sterile field, it must be allowed to cool before use to prevent a patient burn injury. If necessary, the flashed item should be placed in sterile saline to cool the temperature before use.

Depending on the type of sterilizer and the composition of the item to be flashed, specific guidelines from the Association for the Advancement of Medical Instrumentation (ANSI/AAMI) are recommended. The temperature, regardless of the sterilizer, is always 132° C (270° F). The recommended sterilization exposure time ranges from 3 to 10 min and depends on the type of sterilizer and the contents of the load. Drying times of 0–1 min are recommended for gravity-displaced sterilizers, depending on the item and the sterilizer manufacturers' instructions [5, 18].

Quality monitoring of the sterilizer's daily function and each cycle, along with documentation, is a vital part of this sterilization process. The types of monitoring for this process include physical, efficacy, chemical, and biologic rapid readout. Any breakdown in the process, such as incorrect temperature or a positive biologic indicator, must be reported immediately to management and the physician for further follow-up and corrective action.

Education of staff and documentation of competence of the procedure for flash sterilization is another important aspect of this process. Initial and annual training should be provided to all involved personnel, along

with return demonstration by the staff to validate their competency in flash sterilization [18, 19].

To avoid overuse of flash sterilization, it is recommended to increase the inventory of high-volume items that are being flashed, to review the schedule the day before to anticipate the needs of instrumentation, after use to immediately sterilize surgeon or procedure specialty items to allow for sterile availability, and to receive implants in a timely manner to allow for a full sterilization process to take place prior to the procedure start time [19].

Other alternatives

HLD is the other alternative to sterilization in specific healthcare environments. HLD can be expected to kill all microorganisms, with the exception of a few bacterial spores when a high number is present [5, 14]. The steps of this process are similar to those of the sterilization process but do not include packaging or placement of an item in a sterilization container. The steps of this process are cleaning, rinsing, drying, and immersion in disinfectant solution, sterile water rinsing, drying, and immediate use or storage. The Food and Drug Administration (FDA)-approved agents for HLD are 2% glutaraldehyde, stabilized hydrogen peroxide, peracetic acid, and ortho-phthalaldehyde (OPA) [6]. The aldehyde agents are most commonly used for HLD. Glutaraldehyde has an alkaline pH and can be used for 24 weeks depending on the formula, but must be checked daily for potency [14]. Prior to use, staff must don PPE, including a full-face shield, impervious gown with sleeves, and nitril gloves. This chemical disinfectant must be prepared in a well-ventilated area with a low traffic pattern.

Before placement in the disinfectant solution, all items must be rinsed thoroughly to remove any residual detergent, and dried completely to prevent dilution of the disinfectant solution once an instrument is immersed in it [8]. Once an instrument is immersed, if it has lumens or working channels, the disinfectant solution must be flushed through-and-through three consecutive times for internal exposure. Exposure time ranges from 10 to 45 min with a solution temperature of 20–25°C [6]. After the recommended exposure time, the instrument is transferred to an adjacent basin filled with sterile water. The instrument is immersed in this and the external surfaces are wiped with a lint-free cloth. If the instrument has lumens or working channels, the sterile water must be flushed through-and-through three consecutive times to remove any residual disinfectant solution. The final step before use or storage is to thoroughly dry the instrument and, if it has lumens or working channels, air is forced through with a large sterile syringe. For use in a procedure, the instrument should be transferred to a sterile sheet or drape, covered in a sterile manner, and transported to the point of use. If a scope is to be stored, it is recommended that it be hung in a well-ventilated drying cabinet that supplies forced air in cycles. The scope is hung in a vertical position and connected to plastic tubing which enables the transport of forced air. This drying process prevents recontamination from residual fluid that may stay dormant in a scope and harbor bacteria growth, and further promotes thorough drying of the internal channels of an endoscope [6].

According to the AORN, the safest practice in the disinfection of endoscopes is to disinfect at the end of each day's use, again before the first use of the next day and again before each following use throughout the day [20].

Any healthcare facility that utilizes chemical disinfection must provide a safe environment for the set-up and protection of its personnel. The solution once activated and dispensed must be kept in a covered container with a tight-fitting lid, in a well-ventilated area. A free-standing or vented chemical fume hood is recommended for aldehyde solutions. With a free-standing fume hood, a carbon filter is installed and must be changed and disposed of according to the manufacturer's instructions [8]. Fume hoods are available in various sizes and designs to accommodate the facility's needs (Figure 1.4). A spill kit must be readily available in the event of spillage of the chemical solution.

OPA is a newer HLD that was approved by the FDA in 1999. It is less potent than glutaraldehyde, is not an irritant to the eyes and nasal passages, and has a shorter soak time of 12 min. Prior to 2004 this chemical was ideal for the HLD process for flexible cystoscopes, but due to reports of patients experiencing an anaphylaxis-like reaction after a cystoscopy procedure utilizing scopes that were processed with OPA, it is currently contraindicated for cystoscopes. OPA is the disinfectant

Figure 1.4 Table-top and wall-mounted fume hood for aldehyde solutions.

of choice for an ultrasound rectal probe used for guidance during prostate needle biopsy procedures. Prior to the immersion and soak time, an ultrasound probe must be cleaned, wiped or rinsed, and dried according to the manufacturer's guidelines.

Guidelines

Each healthcare facility will determine which method of sterilization is best for its practice. In a hospital setting, steam, gas plasma and peracetic acid are preferred for usage. Some ambulatory healthcare facilities have a steam autoclave, peracetic acid, and aldehydes for HDL as well.

Several organizations have developed guidelines for sterilization and disinfection of instruments and medical devices. AAMI developed recommended practices for steam sterilization in healthcare facilities. The Centers for Disease Control and Prevention (CDC) put together guidelines for disinfection and sterilization in healthcare facilities and guidelines to prevent surgical infections. The Association of Operating Room Nurses (AORN) has recommended practices for cleaning and caring for surgical instruments, sterilization, the use and care of endoscopes and HLD in the perioperative setting. The Joint Commission has standards to reduce the risk of infection associated with medical equipment, devices and supplies; this includes the processes of cleaning, disinfection, sterilization, and storage. In its survey of a healthcare facility, the aim was to document staff orientation, training, and competency in the mentioned processes. Other areas that it will focus on are quality monitoring and adherence to the manufacturer's instruction when processing medical devices or instruments. These organizations' recommendations serve as a resource for a facility's policy and procedure manuals and a guide to best practice.

Conclusions

The ultimate goals of instrument sterilization are to maintain a patient-safe environment, and provide quality patient care and positive surgical or procedural outcomes with no evidence of infections.

CHAPTER 2

How to Protect Patients and Personnel from Radiation

John G. Mancini & Michael N. Ferrandino
Duke University Medical Center, Durham, NC, USA

Introduction

General urology and specifically endourology are heavily reliant upon the use of radiographic procedures for both diagnostic and therapeutic purposes. Computed tomography (CT), magnetic resonance imaging (MRI), nuclear medicine, plain film radiography, ultrasound, and fluoroscopy are integral tools used for diagnosis, therapeutic planning, interventional treatments, and the follow-up of patients. Each has inherent advantages and disadvantages, and therefore the clinical agenda dictates particular imaging utilization. One common drawback for these technologies, with the exception of MRI and ultrasound, is the associated exposure to ionizing radiation. Due to the important role imaging plays in endourology, it is imperative that the creation of, doses administered, and risks associated with ionizing radiation are understood. Despite the essential nature of this knowledge, there is little or no formal education imparted to urologists or residents regarding radiation exposure.

Currently, the issue of radiation dosage is a national hot button topic. Errors in dose administration and the potential risks are national headlines. The Food and Drug Administration (FDA) has recently instituted an initiative to reduce radiation exposure associated with medical imaging below present levels (http://www.fda.gov). Manufacturers of new devices are required to comply with the Federal Food, Drug and Cosmetic Act's Electronic Product Radiation Control. Furthermore, devices already in use are legally required to be routinely tested to assure adequate function and safety, and these findings are to be logged with the FDA. Even with the regulatory guidelines, much of the burden of patient, employee, and physician protection falls upon the physician and administrator.

Typically, dose production for a CT, fluoroscope, or plain radiographic device does not vary for a given set of parameters; however, the settings chosen can be greatly altered to affect the output. Hence, the technician or physician performing the studies has direct control over patient and operator dosage. Therefore, it is up to the endourologist and technician to decide the balance between exposure and image quality. Additionally, the necessity of any imaging modality must be weighed. Consideration of each test's utility, the information to be gained, and how it will affect management are critically important. No radiographic study should be ordered without consideration of alternative imaging studies which may yield similar or superior information at lower radiation exposures.

A common theme in the practice of radiation protection is ALARA – *a*s *l*ow *a*s *r*easonably *a*chievable. The goal of this axiom is to minimize exposure to both patients and workers while obtaining the maximal benefit possible. The key methods of exposure limitation are time, distance, and shielding. Logically, minimization of imaging techniques associated with ionizing radiation is critical.

This chapter intends to briefly explain the rationale for concern over radiation exposure and potential risks. Additionally, we intend to describe the sources of X-ray production, estimates of exposure for various imaging techniques, and methods of protection and exposure minimization.

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Table 2.1 Typical doses and chest X-ray equivalents of common urologic imaging procedures.

Examination	Typical effective dose (mSv)	Number of chest X-ray equivalents
Chest PA	0.02	1
KUB	0.7	35
IVP	2.4	120
CT chest	8.8	400
CT abdomen or pelvis	10	500
PCNL	9	450
URS	2.5	125
SWL	1.6	80

KUB, kidney–ureter–bladder film; IVP, intravenous pyelogram; CT, computed tomography; PCNL, percutaneous nephrolithotomy; URS, ureteroscopy; SWL, shock-wave lithotripsy.

Background

Exposure to radiation is typically measured and reported in units of Gray (Gy). One Gray is directly proportional to joules of radiation absorbed per kilogram of tissue. However, this unit of measure is inadequate for estimates of risk because it does not take into consideration the relationship between absorption and tissue sensitivity. By using tissue sensitivity, the effective dose can be calculated and is expressed in Sieverts (Sv). Standard nomenclature describes the dose administered in milliSieverts (mSv) because the doses used for radiographic imaging are generally very low. Average medical imaging exposures can range from 0.7 mSv for a single plain abdominal film to upwards of 18 mSv for a CT scan, depending upon device settings and body habitus (Table 2.1). In comparison, naturally occurring background radiation exposure is 2–3 mSv annually.

Even with the relatively low associated doses, the concern over radiation exposure has grown recently due to the exponential rate at which medical imaging is used [1]. The risks of exposure can be categorized as deterministic or stochastic. Deterministic effects generally result in direct cell death from high doses directly administered to biologic tissue. Stochastic effects are those wherein the likelihood of an event increases with dose. Deterministic risks of excessive exposure range from entry site erythema, to cataracts, to desquamation and depilation. Diagnostic imaging is rarely associated with these side effects, but interventional procedures may exceed these thresholds [2]. The stochastic risks of greatest concern are increased potential of solid and hematologic malignancy. These risks are not inconsequential, particularly when considering accumulated lifelong exposures from the repeated studies which many patients undergo. There is a clear correlation between excessive exposure and the deterministic dermal and ocular effects. Debate, however, exists regarding the models used to calculate the stochastic side effects associated with radiation exposure.

Radiation production

Prior to understanding methods of protection, it is prudent to understand the principles of radiation physics and production. In this section we will briefly review the topic of radiation generation. A full detailed description is beyond the scope of this chapter but is readily available in radiation physics texts.

The basic components required for the generation of X-rays are two electrodes (an anode and cathode), a high voltage source, and an X-ray tube. Additionally, sources of radiation generation include a housing, which provides shielding and a collimator, which specifies the X-ray field. Within the shielded housing, electrons move from the cathode to the anode due to the potential difference created by the high-voltage source. As these electrons transfer, they gain kinetic energy in a ratio directly proportional to the potential difference between the cathode and anode [i.e. 20 kilovolt peak (kVp) = 20 kiloelectron volts (keV)]. The kinetic energy gained by the electrons as they cross from the cathode to the anode is then converted to other forms of energy upon impact with the anode. The vast majority of this kinetic energy is converted to heat. The remainder of the energy is converted into X-ray photons. This occurs when the electron comes close to the positively charged nucleus of the anode's material. Each X-ray photon is equal to the kinetic energy lost by these high-energy electrons.

The amount of radiation generated by individual electrons varies depending upon the proximity to the target material's nucleus. A direct impact transfers a large quantity of the kinetic energy and therefore generates maximum energy X-ray photons, while a more distant interaction generates weaker photons. The X-ray photons, or radiation, produced is termed bremsstrahlung, which translates to "braking radiation." The variability of distance from the nucleus therefore creates a spectrum of energy emitted from the X-ray tube, the bremsstrahlung spectrum. The mean energy of the photons across the spectrum is typically equal to one-third the total potential difference generated by the voltage.

The energy of photons is an important consideration because the higher the energy of the photon, the more shielding is required and the more readily the photon will penetrate tissue. Shielding levels for the X-ray housing are federally regulated to less than 100 mrad/h at 1 m to prevent excessive leakage rates while the tube is operating at maximum potential difference and

current. The photons leave the tube through a small opening in the shielding and are directed towards the area of interest. Filters are then generally applied to these diagnostic X-ray beams. These filters attenuate the lower energy photons which do not have sufficient energy to reach the detector and therefore are not of clinical benefit. The electrons with energy high enough to penetrate through the filters are focused by the collimator through the tissue area of interest. Typically, the collimators further restrict exposure to the patient and the operator by eliminating radiation exposure outside the area of interest.

The quality of the image obtained is significantly dependent on the energy level and quantity of the electrons reaching the detector. The X-ray photons need to be of high enough energy to penetrate through the tissue but low enough to limit "over-exposure" of the detector. Therefore, the most controllable aspects of diagnostic imaging equipment are: the potential difference (kVp), which determines the amount of energy in X-ray photons; the current (mA), which determines the number of electrons that create photons for a given time period; and exposure time, which combines with the current to determine the total quantity of X-rays produced (mAs). Because exposure is proportional to the square of kVp and linearly related to mAs, it is optimal to increase kVp prior to increasing mAs to increase an image's exposure. Conversely, if an initial image is "over-exposed," reducing mAs will more greatly reduce radiation dosages.

Understanding the basic principles and mechanisms of X-ray generation provides a foundation for the understanding of radiation protection. Proper equipment maintenance and inspection of shielding and filters are requisite parameters for operators of imaging equipment. An understanding of the electrical parameters and their effects on X-ray generation can lead to optimization of the image quality while minimizing dose to patients and operators. Finally, the use of collimation to limit the exposure field to precisely the tissue area of interest can greatly restrict unnecessary exposure.

Risks of excessive radiation exposure

As mentioned earlier, the risks of excessive radiation can be divided into two general categories: deterministic effects and stochastic effects. Deterministic effects are due to radiation-induced cell death and occur after a relatively large radiation dose. These effects include cataracts and skin injury. The radiation dose thresholds for developing erythema and more severe skin injuries are relatively well-established. Doses of 300–600 rad can cause temporary depilation and erythema, while 1500–2000 rad can cause desquamation, dermal necrosis, and ulceration [2]. The minimum dose that has been shown to produce a progressive cataract is 200 rad. Normally, in modern diagnostic and interventional imaging, the doses delivered are well below these threshold levels.

Stochastic effects occur by chance without threshold levels. The probability of an effect is associated with dose, but the severity is independent of dose. The main stochastic risk of increased radiation exposure is the development of hematologic or solid malignancy. The level of radiation exposure that is dangerous remains controversial with two diverging theories: linear no-threshold model (LNT) and hormesis theory. In the LNT model, radiation exposure is considered additive over time and linearly extrapolated to determine risk. The risk of developing malignancy is directly related to the cumulative amount of radiation exposure. Alternatively, the hormesis theory suggests that at low doses, radiation exposure is not damaging, but actually may serve a protective role. This model hypothesizes that below a certain threshold level, ionizing radiation will not contribute to an increased risk of malignancy [3].

The more widely accepted and more prudent theory is the LNT model. The estimated risk of malignancy, according to the LNT model, is based primarily on data from approximately 35 000 atomic bomb survivors and 400 000 nuclear industry workers. These calculations estimate an excess relative risk of 0.32–3.15/mSv depending upon the type of malignancy for nuclear industry workers and atomic bomb survivors [4]. Furthermore, epidemiologic analysis from these data shows a risk of radiation induced fatal cancer of 5%/Sv for the general population [5]. More specifically, certain risk models take into account the type of radiation, dose, and age and sex of patients exposed. For example, a 25-year-old man exposed to a one-time dose of 10 mSv of ionizing radiation would have a 0.05% chance of developing a lethal cancer, compared to a 0.02% chance for a 45-year-old man under the same circumstances. The baseline risk of developing malignancy from all causes is approximately 20% over a lifetime. Thus, for the 25-year-old in this example, his overall risk would increase to 20.05%. This increase in risk, while low, becomes more significant with younger age of exposure and exposure accumulation over the patient's lifetime. The use of CT scans, which currently represent the most significant contribution to a patient's medical radiation exposure, has risen three-fold since 1993, up to 70 million scans a year. Despite low individual risks, the increasing exposure to the population is projected to create a relatively large number of cancers. In fact, Brenner and Hall suggest that nearly 0.4% of all current cancers in the USA may be attributable to CT usage [1]. Additionally, in a recent report, de Gonzales *et al*. estimated that 29 000 future cancers could be attributable to ionizing radiation produced by CT scans in the USA in 2007 [6].

Using this model, the International Commission on Radiological Protection (ICRP) has set forth recommendations limiting *occupational* exposure to 50 mSv in any given year or 20 mSv/year over a 5-year period [5]. National and international organizations, including the US National Council on Radiological Protection and Measurements, the US National Academy of Sciences Biological Effects of Ionizing Radiation, and the ICRP, among others, unanimously agree that for radiation doses less than 100 mSv, the LNT is the most appropriate risk model [7].

It must be emphasized that these guidelines are for occupational exposure and do not provide any more than a framework for the practicing physician. There typically is a significant benefit gained from the exposure associated with medical imaging. Proper diagnosis can lead to proper management and optimal medical care.

Sources of ionizing radiation encountered in urology

Diagnostic imaging

It is well accepted that the utilization of medical imaging is inseparable from the evaluation of most patients and complaints. The ability to visualize anatomic and functional complaints greatly enhances the clinician's ability to care for individual patients. Unfortunately, many of the most commonly utilized modalities incorporate ionizing radiation to attain the necessary images. Plain film radiography, CT, and nuclear medicine studies all expose patients to various doses of radiation. Only ultrasound and MRI avoid such exposure, but these too have their own limitations.

Traditionally, plain radiography with a kidney–ureter–bladder (KUB) film has been the initial imaging modality for many patients with urologic complaints. In patients with nephrolithiasis, the majority of stones contain calcium and therefore will be readily apparent on plain radiograph. Certain stone compositions, most notably uric acid, will not appear on KUB. The identification of stones can be further complicated by overlying bowel gas, extraluminal calcifications, and patient body habitus. The advantages of KUB are low cost, worldwide availability, and a low effective radiation dose of 0.2–0.7 mSv. The sensitivity and specificity for detecting urinary stones is reportedly 59% and 71%, respectively [8].

Intravenous pyelogram (IVP) has benefits similar to KUB, and offers added information regarding anatomic detail and function. The use of contrast allows for the identification of key structures. As contrast fills the collecting system and ureter, the presence and location of urinary tract obstruction can be evaluated. Additionally, renal and urothelial masses and urolithiasis can be evaluated by IVP with special attention paid to the contour of the collecting system and the presence or absence of filling defects. IVP is associated with improved sensitivity and specificity to detect stones over KUB alone, reported as 64% and 92%, respectively [9]. The estimated effective radiation dose is 0.7–3.7 mSv, based on the number of images obtained [10]. The main drawbacks of IVP are a relatively long procedural length and the need for intravenous contrast, with its associated risk of contrast-induced nephropathy and allergic reaction.

CT is widely used in the diagnosis and follow-up of many urologic conditions. It is currently the ideal test for assessment of renal masses and renal cystic disease. CT urogram has largely replaced IVP for assessment of ureteral abnormalities. Additionally, CT is routinely employed in the metastatic work-up of virtually all urologic malignancies. Unenhanced CT is the gold standard for the diagnosis of urinary stones with sensitivity and specificity of near 100% [11]. Additionally, in the evaluation of a patient with acute flank pain where a ureteral stone is suspected, CT can suggest alternative diagnoses. In a retrospective review of 1000 patients evaluated by CT, Katz *et al*. found 101 exams revealing alternative or supplementary diagnoses [12]. As with all diagnostic studies, CT has its pros and cons. CT provides excellent anatomic detail, but is associated with a higher relative cost, less widespread availability, and a high effective radiation dose of 4.5–18 mSv [10].

For patients with nephrolithiasis, radiographic imaging is inseparable from accurate diagnosis, treatment, and follow-up. To quantify patient exposure during a single stone episode, John *et al*. performed a retrospective analysis in the UK, where CT is not routinely used. Of the 60 patients included in the study, only 14 had CT scans. The patients received a median effective dose of 5.3 mSv (1.18–37.66 mSv). Notably, those patients who underwent a CT scan received significantly higher exposure levels than those who did not (14.46 mSv vs. 4.25 mSv) [13]. More recently, we reported the radiation exposure associated with an acute stone episode and 1 year of follow-up at two academic centers in the USA and found the median effective radiation dose to be 29.7 mSv, with 22 of 108 patients (20%) receiving over 50 mSv. In the group that received over 50 mSv of radiation exposure, the average number of CT scans was 3.5 [14]. One limitation of the study was that it did not include radiation exposure from interventional imaging, which may be a significant contributor to a patient's overall exposure profile.

Interventional imaging

Fluoroscopy is the main interventional imaging modality used by urologists. It allows for realtime imaging in

many urologic procedures, including percutaneous nephrolithotomy (PCNL), retrograde pyelography, ureteroscopy, and shock-wave lithotripsy (SWL). In a recent study, the mean effective dose for PCNL was 9.2 mSv (0.82–26.0 mSv) [15]. In an ongoing study at our institution, we found the mean effective dose during PCNL to be 9.09 mSv (0.46–51.6 mSv), with body mass index (BMI), stone burden, nonbranched stone configuration, and number of percutaneous access tracts to be associated with increased radiation dose [16]. The mean effective dose for ureteroscopy has been previously reported as 2.5 mSv, with exposure being higher when flexible endoscopes were used compared to semirigid devices; and highest when both devices were utilized in the same setting. The authors proposed that this effect is likely related to the increased complexity of the case. They additionally noted that radiation exposure was higher in therapeutic procedures compared to diagnostic procedures [17]. In a recent study of 50 SWL cases, the mean effective dose to the patient was 1.63 mSv, with a mean fluoroscopy time of 204 s [18]. The factors associated with increased radiation exposure during SWL were increasing stone burden, patient weight, and ureteral (as opposed to renal) stone location [19].

Dose reduction strategies

There are numerous methods to reduce radiation exposure to patients, beginning with the elimination of unnecessary studies, proper radiation safety education, and the optimization of modalities that do not use ionizing radiation, such as ultrasound and MRI. Unnecessary radiographic imaging has plagued modern medicine. One study in the pediatric literature suggests that up to one-third of all CT exams could be eliminated or replaced by alternative approaches [20]. Therefore, judicious use of imaging alone could significantly reduce dose to patients. Additionally, success in reducing radiation dose has been shown with the implementation of a "radiation awareness program," where focus was placed on taking fewer "snapshots" during SWL [21]. Also, after implementing a radiation safety education initiative, one group noted significant decreases in dose area product and fluoroscopy time for several of their most common pediatric procedures [22]. By optimizing usage of imaging procedures that do not use ionizing radiation, such as ultrasound and MRI, urologists can greatly reduce overall dose to patients.

Ultrasound has recently gained acceptance as a modality for obtaining access to the collecting system during PCNL. When it is utilized for access purposes, there is a significantly reduced fluoroscopy time. The use of ultrasound was, however, associated with a longer overall procedural time [23]. Additionally, ultrasound can be combined with other imaging modalities, such as KUB, and together used in place of CT. Catalano *et al*. compared CT to the combination of KUB and ultrasound for the evaluation of renal colic and concluded that, though CT showed better sensitivity (93% vs 77%), specificity was comparable (96% vs 93%). Of the 48 patients who underwent KUB and ultrasound, six (12.5%) had false-negative results. However, all six patients with false-negative results had uncomplicated courses with spontaneous stone passage [24]. Therefore, the combination of KUB and ultrasound has good practical application and is a viable alternative when CT is contraindicated, unavailable, or otherwise less preferred.

MRI or magnetic resonance urography (MRU) is a technique that produces no ionizing radiation and can be used to evaluate the genitourinary system. MRI previously had a significant role in chronic kidney disease patients where iodinated contrast with a CT or IVP was contraindicated, but it too is now contraindicated in patients with renal impairment secondary to gadolinium's association with nephrogenic systemic fibrosis. MRI provides excellent anatomic detail and can be used without concern in pregnant patients. However, it is a poor exam for the evaluation of stones, as their appearance is that of a signal void, similar to blood clots and tumors. For ureteral stones, multiple studies have demonstrated that MRU can rapidly and accurately determine the level and degree of ureteric obstruction, as well as the presence of perinephric fluid [25, 26]. A study combining CT and MRU showed a detection sensitivity of 98% and that a marked reduction in effective radiation dose to 0.52 mSv can be obtained. This report utilized MRU to identify the level of obstruction and a subsequent targeted CT to characterize the cause of obstruction [25]. Though this combination shows high sensitivity with minimal radiation exposure, it may have minimal clinical applicability because it is time-consuming, expensive, and MRU is not widely available.

Dose reduction strategies in CT

In the current urologic and medical landscape in general, the majority of patient radiation exposure is derived from diagnostic and follow-up imaging procedures via CT scanning. As CT is widely regarded as the optimal diagnostic modality for the evaluation of patients with stone disease and indicated for the follow-up of many urologic diseases, efforts have moved toward reducing the radiation dose associated with these studies. Strategies to reduce radiation exposure can be broadly classified into two groups. First are strategies associated with the basic design of scanners and their components, including the efficiency of detectors and X-ray tube characteristics. Second, there are a number of technical

parameters that can be modified by the radiologist or technician to reduce radiation exposure, including pitch, slice thickness, and tube current.

Pitch, the speed at which the table moves through the scanner gantry, can be adjusted to decrease radiation dose, whereas increasing pitch will decrease radiation dose. In a single-slice helical CT, moving from the standard pitch of 1 to 1.5 causes a 33% reduction in effective dose, while still maintaining adequate image quality [27]. However, this correlation between pitch and dose does not hold true in all multislice scanners. One study showed no difference in measured radiation dose through all pitch selections, because of an automatically proportionate increase in tube current applied by the multislice scanner [28].

Slice thickness is another parameter that can be adjusted to potentially reduce radiation exposure. In general, thinner slices will provide more information, but also expose the patient to a higher level of radiation. The goal, therefore, is to optimize slice thickness to find clinically relevant pathology without exposing the patient to excessive radiation. For the diagnosis of nephrolithiasis, one study showed 70% more stones detected with 0.5-mm slices compared to 5-mm slices, but at the cost of markedly increased radiation exposure [29]. The current consensus is that 2.5-mm slices are adequate for the detection of most clinically relevant stones. Also, by increasing the number of detectors on a multidetector CT scanner, the changes between slice thickness have less effect on radiation dose. For example, with a four-detector device, moving from 1-mm slices to 2.5-mm slices would decrease the effective radiation dose by 30%. The same change in a 16-detector device would lower the dose by 10%. A 64-detector device would show no change in radiation dose when moving between different slice thicknesses [30]. This can, however, be misleading, because as a general rule, increasing the number of detectors will increase radiation dose due to thinner slice collimation [31].

The most significant way to reduce effective radiation dose is by reducing tube current. Many CT scanners utilize dose modulation software which adjusts the dose based on patient body habitus, and the density of tissues penetrated by radiation. The software uses the scout image to make adjustments in radiation output, decreasing radiation dose in thinner, less dense parts of the body. Reduction in tube current will, however, produce images with more "noise." For certain imaging purposes, such as the detection of urinary stones, which are high-contrast objects, a higher level of "noise" is acceptable without limiting diagnostic capabilities.

Low-dose CT scanning has been developed that accepts a relatively high level of "noise" in return for a marked reduction in radiation dose. Multiple studies have shown that low-dose CT can produce equivalent sensitivity and specificity in detecting nephrolithiasis when compared to standard CT. Ciaschini *et al*. showed comparable sensitivities between standard CT and simulated CT reconstructions at 50% and 75% reduction from the original dose for stones greater than 3 mm [32]. Another study showed similar detection ability with low-dose CT for stones greater than 2 mm, with a reduction in radiation dose of 81%, to a mean of 1.4 mSv for men and 1.97 mSv for women [11]. Also, Polletti *et al*. studied 125 patients with renal colic who were evaluated with both standard and low-dose CT scans, where men received an estimated 9.6 ± 1.2 mSv and 1.6 ± 0.2 mSv, and women 12.6 ± 1.8 mSv and 2.1 ± 0.3 mSv, respectively. For patients with a BMI of less than 30 kg/m^2, the sensitivity was 95% and specificity was 97% for detecting ureteral calculi of all sizes. In patients with a BMI of 30 kg/m^2 or greater, the sensitivity of low-dose CT to identify ureteral stones was 50%. Of note, there were only 13 patients with a BMI of 30 kg/m^2 or greater, and of the stones that were not identified, only one was greater than 3 mm [33]. Though the number of obese patients in this study is small, these results are consistent with other studies, highlighting the notion that low-dose CT may be limited in the obese population and may fail to identify stones smaller than 2–3 mm.

In contrast, Mulkens *et al*. demonstrated comparable sensitivity, specificity, and accuracy between standard and low-dose CT across all BMI ranges with the use a 16-detector CT and tube current modulation. The standard CT had a relatively low mean effective dose of 2.89 mSv, which was decreased 51% further to a mean effective dose of 1.41 mSv, with low-dose parameters applied. The tube current modulation software caused the dose range to be quite variable, 0.73–2.7 mSv in the low dose group, with a direct correlation noted between effective dose and BMI (Spearman coefficient 0.86–0.88) [34]. The results of this study show that with modern equipment, obese patients require a higher, but overall relatively low, radiation dose for accurate detection of urinary stones. These studies utilizing low-dose CT appear to show exciting promise. Extreme dose reduction is only appropriate for nonobese patients and even then, the ability to detect very small stones may be limited. However, it appears that moderate dose reduction can be achieved with adequate detection ability even in obese patients.

While much of the dose reduction work focuses on patients with nephrolithiasis, patients with malignant diagnoses undergoing surveillance protocols or follow-up imaging would also likely benefit from minimization of exposure. The optimal parameters for patients in these situations have yet to be determined but is a potential future research direction.

Dose reduction strategies with fluoroscopy

In 1995, the FDA began regulating the maximum output of fluoroscopy units with specific levels set for normal (10 rad/min) and boost (20 rad/min) modes. These outputs are achieved by the maximum potential energy (120 kVp) and current (2 mA) settings. Therefore, since most fluoroscopy units generate similar radiation profiles, the radiation exposure to patients and operating room personnel is dependent on the operator and type of procedure.

Fluoroscopy exposure during PCNL is associated with a mean effective radiation dose to patients of approximately 9 mSv, approximately the equivalent of a standard abdominal CT scan. The range of exposure from one study was broad, with several patients receiving greater than 50 mSv [16]. Therefore, fluoroscopy during interventional procedures can be an important contributor to a patient's overall radiation exposure profile. A number of improvements have been made by manufacturers of fluoroscopic imaging equipment in recent years with the goal of producing the highest quality image with the lowest possible radiation dose. These improvements include the use of low attenuation materials, such as carbon fiber, in table tops and cassettes, improved energy spectra produced by high-frequency generators, and additional filters to reduce entrance skin dose. Equipment design and component position can influence scatter and leakage radiation. With the X-ray tube located under the fluoroscopy table and the image intensifier above the table, most scatter and leakage radiation is shielded by the table itself and will not cause significant occupational exposure. Also, features such as last image hold, pulsed fluoroscopy, and digital imaging have contributed significantly to lowering patient exposure. Last image hold enables the last image produced to be maintained on the monitor as opposed to a blank screen, limiting unnecessary re-exposure. With the advent of digital imaging, pulsed fluoroscopy is possible. In continuous mode, pulsed fluoroscopy, refreshes the image at a rate of 30 frames/s. This can result in an 80% reduction in radiation dose over traditional, continuous imaging without impacting image quality. Additionally, by adjusting the device to a pulse rate of 15 frames/s, radiation dose can be further reduced [35]. These features are inherent to the device and many are automatically selected.

There are also several factors that are under the control of the operator and can be further maximized to limit radiation exposure, highlighting the importance of a well-trained and experienced fluoroscopist. They include acquiring as few images as possible, precisely collimating the beam to the region of interest, limiting the use of magnification, and strict adherence to the ALARA principles.

Protection from ionizing radiation

The basis of the ALARA concept is the avoidance of unnecessary radiation. Because of the valuable information gathered from radiographic studies, a key concept of the ALARA principle is that the avoidance of exposure must be reasonable in that it does not hinder the performance of the study, is not high cost, is not overly time-consuming, and offers a significant reduction in exposure. The basic principles of ALARA are time, distance, and shielding.

Time

The most efficient and effective way to limit radiation exposure to patients and healthcare personnel is to limit the time of the study. When using fluoroscopy, it is important to capture images only when necessary. Many authors have admitted that it is easy to let the device run continuously, even for the smallest step in a procedure. Also, it is best to have the surgeon operate the on–off function of the device by using a foot pedal. If this is not possible, it is imperative to have a well-trained and experienced fluoroscopist and effective communication between the fluoroscopist and the surgeon. Reducing the amount of time spent in the vicinity of the device also decreases the amount of radiation exposure for those performing and assisting in the procedure. Those individuals who are not actively tending to the patient should not spend time near the fluoroscopy equipment while it is in use. Several advances that have been discussed previously – last image hold, digital imaging, and pulsed fluoroscopy – are all ways in which fluoroscopy time can be reduced. In one study, conversion from a film screen to digital fluoroscopy with last image hold showed a radiation dose reduction of 70% [36].

Distance

X-rays act like visible light and other electromagnetic waves in that they spread out in three-dimensional space as distance increases. As a result, the area geometrically increases as a function of distance from the source and radiation exposure becomes inversely proportional to the square of the distance – the law of the inverse square. By doubling the distance, the radiation exposure is decreased by a factor of four. By tripling the distance, the exposure is deceased by a factor of nine. At a distance of 12 feet from the source, the radiation dose is reduced to background levels. Distance represents one of the easiest ways to limit exposure to operating room personnel, and therefore, those individuals who are playing noncritical roles should separate themselves from the procedure.

Shielding

Once time and distance have been optimized, the next level of protection is shielding, in particular for those persons who are required to be within the region of exposure. Shields are usually made of heavy metals, most commonly lead, that can effectively attenuate radiation. Shields can be part of personal protection in the form of lead aprons, thyroid shields, eyeglasses, and gloves, or incorporated into room design, such as a ceiling-mounted shield. Most aprons are 0.5-mm equivalent lead thickness and attenuate radiation by 96.5–99.5% for the potential energy range most encountered during fluoroscopy (70–100 kVp). Movable transparent lead shields and drapes can also be used to further reduce exposure to individuals operating close to the radiation source. One group designed a urologic surgery radiation drape to be used for endourologic procedures that reduced radiation dose to the urologist by 70-fold over apron and thyroid shielding, but this drape was not widely accepted as many thought it was too cumbersome [37]. Overall, shielding can effectively be used as the last line of defense, with only very minimal impact on the tasks being performed.

Conclusions

Urologists deliver and prescribe a great deal of ionizing radiation to their patients. This exposure comes with meaningful, albeit small, risk. Great strides have been made on numerous fronts to reduce radiation exposure. However, additional work needs to be done, as certain patients are still being exposed to excessively high radiation doses. The urologist must understand radiation safety in order to protect the patient, themselves, and the operating team from potential radiation injury. The importance of the ALARA concept, minimizing time, maximizing distance, and the appropriate use of shielding, cannot be overstated. Ultimately, there are several important ways to reduce patient and provider radiation exposure. First, we must be certain that proper justification exists for an imaging study or procedure. Second, we must consider alternative means of imaging, when clinically appropriate. Last, we must work in conjunction with radiologists to balance radiographic image quality with radiation dose, especially in stone patients where the use of low-dose CT appears promising. Communication between the ordering physician and radiologist is critical to determine the most ideal imaging parameters needed to answer a particular question, ensuring that the lowest possible radiation dose is administered. It is the responsibility of all physicians, including urologists, to implement ways to reduce radiation dose without compromising patient care.

CHAPTER 3
Video Imaging and Documentation

Michael E. Lipkin, Charles D. Scales Jr, & Glenn M. Preminger
Comprehensive Kidney Stone Center, Duke University Medical Center, Durham, NC, USA

Introduction

Innovations and improvements in video imaging technology have paved the way for significant advances in endourology and minimally invasive urologic surgery. Recent advances in technology have turned what once appeared to be science fiction into reality. Virtual reality simulators, three-dimensional video imaging, telementoring, and video image overlay are all being incorporated into current surgical practices. These technologies are not only facilitating the performance of complex surgical procedures, but are also allowing wider dissemination of the skills needed to perform these procedures. As these technologies continue to develop, their applications in minimally invasive endourologic practice will only grow.

This chapter will review the current state of the art of video imaging and documentation systems within endourology. Technologic advances and their application in current endourologic practice will be discussed. It is anticipated that this information will not only help the reader to enhance their video imaging practices today, but also prepare them for tomorrow's tremendous innovations in advanced imaging modalities.

Digital imaging

A number of major improvements have greatly enhanced videoendoscopic surgery [1–3]: the development of the charged coupled device (CCD) chip camera and the introduction of digital video imaging. Once an optical image is focused on the CCD chip, there is a conversion of the optical (light) image to an electronic signal [4]. This electronic information, which includes both color and light (luminance), can be scanned by a video monitor to produce an image on the screen.

Standard National Television Systems Committee (NTSC) video signals utilize a limited "bandwidth," which includes both the color and luminance information in a single or "composite" signal. Problems with this format include "signal noise," which is caused by the camera having to first process color and luminance information separately and then combine the two pieces of information to create a video signal. This video noise or "cross talk" may be the cause of decreased resolution, grainy images, and loss of information around the edges of the video image. Moreover, this video noise will increase as additional copies of the video tape are produced.

With the advent of digital imaging, two newer video formats have been introduced [5]. The first format allows the color and luminance information to be carried as two separate signals. This "component" video signal is called Y/C, with Y standing for luminance or light brightness and C referring to color. Also known as SuperVHS (or S-VHS), this component signal contains less cross talk and therefore appears cleaner and sharper than images generated by composite signals. The video signal in a Y/C format is carried by a single cable, as with the NTSC format, although the color and luminance information are still separated.

The final digital video format is known as RGB (red–green–blue). This RGB format is also a component signal, yet it is distinct from the Y/C format in that the video information (color and luminance) is separated into four signals. These include a red, green, and blue

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

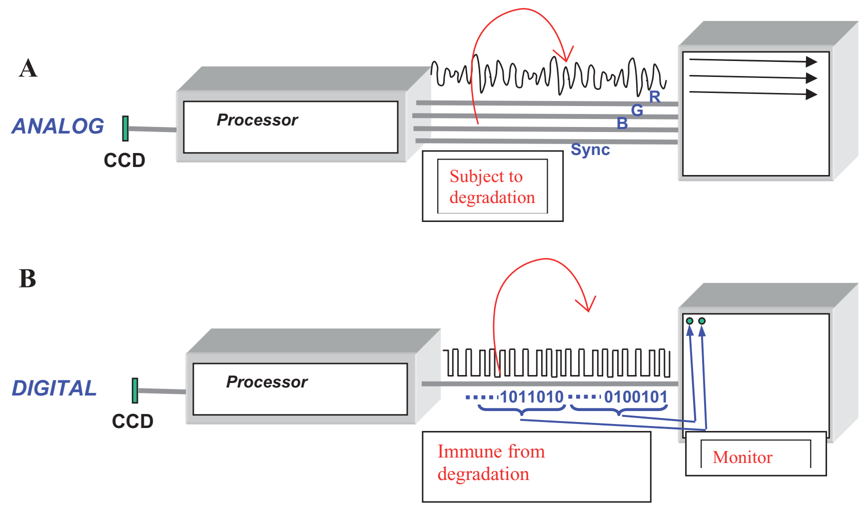

Figure 3.1 (A) Representation of analog video imaging in which video signals remain as voltage waveforms. (B) In contrast, digital video systems convert the analog video information to a digital format, which must then be converted back to analog information before it is viewed on the video monitor. Conversion to a digital signal gives the digital video image immunity to noise build up or image quality degradation.

signal as well as a timing signal. Each individual signal carries its own luminance information. Separation of the video signals is performed electronically in the camera head. The RGB format requires less electronic processing than do the NTSC or Y/C formats since the color and luminance information are separate from the start. Therefore, the RGB image quality is greatly enhanced as compared to the other two formats. Also, in contrast to the single cable NTSC and Y/C formats, the RGB video signal is carried by four separate cables (red–green–blue and sync). While most video monitors will accept standard NTSC video formats, a special (and more expensive) monitor is required to accept Y/C and RGB formats. The increased price, however, will result in a far superior image to standard NTSC formats.

In standard analog video processing (NTSC format), images or signals remain as voltages (Figure 3.1A). Small errors in recording and reproducing these voltages are inevitable and the errors accumulate with each generation of the video image. Hence, multiple copies of an analog image will reveal a decrease in the quality of the video pictures. In contrast, a digital convertor changes all video signals into precise numbers (e.g. 0 or 1) in the digital video formats (Y/C and RGB) (Figure 3.1B). Conversion to a digital signal gives the video image immunity to noise build up or image quality degradation. Moreover, image processing can be performed to enhance (and in some cases, alter) the digital video images. Once the video information has been digitized, it can be merged with other formats (text, data, audio, etc.), transmitted or copied, with no loss of information.

Standard video systems

The technical advantages created by video monitoring include binocular vision and magnification of the monitor images. Magnification may be as great as 20 times, depending on the initial optics system used. This enlarged image permits better inspection of detail and allows the operator, by virtue of the enlarged image size, to perform the procedure off the monitor rather than looking directly through the endoscope [6]. This approach significantly decreases operator strain because the surgeon no longer needs to conform their body to the angle of the viewing lens. Instead, the urologist can simply attach a video camera to the scope and manipulate the endoscope while standing comfortably and observing the video monitor [3]. Moreover, the upright position assumed by the urologist decreases the likelihood of coming into contact with potentially infected body fluids.

Video cameras

All video systems are currently composed of a CCD solid-state chip camera, a video processor with or without a video recorder, and various video accessories. All of the chip cameras are fully immersible and shielded from electrical interference that may be created by cutting or coagulating currents during endoscopic procedures [7]. The CCD chip high-resolution camera should have an automatic white balance feature which allows one-touch color balance, assuring true to life color reproduction. Additional features of the CCD

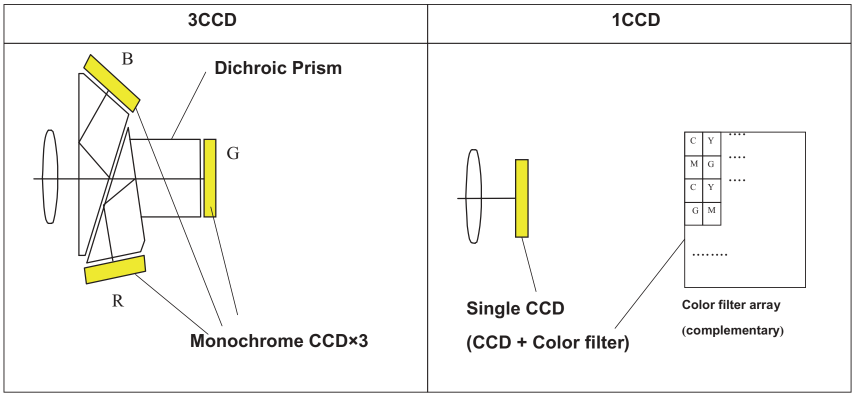

Figure 3.2 Schematic representation of three- and one-chip charged coupled device (CCD) designs. Red, green, and blue sent to three separate CCDs by a prism.

camera may include a high gain option which will boost the video signal to provide an exceptionally clear image, as well as a color bar option that allows the surgical team to adjust the monitors to represent accurate camera color prior to beginning the case.

Advances in CCD camera technology have significantly downsized current endoscopic video cameras, thereby allowing easier movement of the endoscope with the attached camera. With the recent significant improvements in CCD technology, tube cameras are no longer utilized due to their large size. When recording an actual endoscopic procedure, the camera may provide a remote control switch for a video recorder, allowing instant fingertip pausing of the recording device during documentation. Additionally, the camera head should be designed to prevent fogging between the coupling device and the camera head. All manufacturers can supply camera head adapters for other endoscopic systems. Finally, the entire camera head cable and edge card can be completely cold soakable in disinfectant solutions for easy sterilization between endoscopic cases.

As noted previously, CCD chip cameras have supplanted the tube cameras which were the first video systems on the market. A significant improvement in CCD camera technology has been the development of the three-chip camera that contains three individual CCD chips for the primary colors – red, green, and blue (RGB) (Figure 3.2). In addition to composite S-VHS and component signals, the three-chip cameras also provide an "uncoded" RGB signal. Color separation is achieved using a prism system overlying the chips [8]. This three-chip camera design provides improved color fidelity and enhanced image resolution. Moreover, three-chip cameras produce less "noise" due to the pure RGB signals [9, 10]. A digital converter captures each voltage signal as an image and translates the voltage values into discrete numbers, either as 0 or 1. The encoded numbers for each image element, or pixel, include information on color, light intensity, and contrast. These variables can then be modified using image-processing software within the camera [11].

In theory, three-chip cameras produce better quality images than single-chip cameras. Despite the apparent advantages of three-chip cameras, some clinical comparisons have favored one-chip systems. Using normal video monitors, previous studies have implied that the resolution between the two cameras did not alter the visual perception of an image. Studies have found that digital contrast enhancement is a more important feature for endoscopic imaging than the number of camera chips. Three-chip cameras appear to have no advantage over well-designed single chip systems [8, 12, 13] However, this apparent limitation may change with the introduction of high-resolution digital monitors and high-definition television (HDTV), as the amount of image information and the degree of perception are increased with these digital imaging modalities [14; see below].

Many of the CCD chip cameras (both single- and three-chip) contain electronic shuttering mechanisms that automatically adjust exposure time from 1/60 to 1/16 000 of a second. The advantage of such a sophisticated detection circuit is that the camera can react to varying light conditions almost instantaneously, reducing the flaring, "washout," and "blackout" which were noted with early video systems. Moreover, electronic shuttering mechanisms within the camera usually work more quickly than automatic light sources.

Videoendoscopes

A major advance in the endoscopic systems has been the development of the digital videoendoscope. Miniaturization of chip technology now allows a CCD chip to be incorporated at the distal end of the

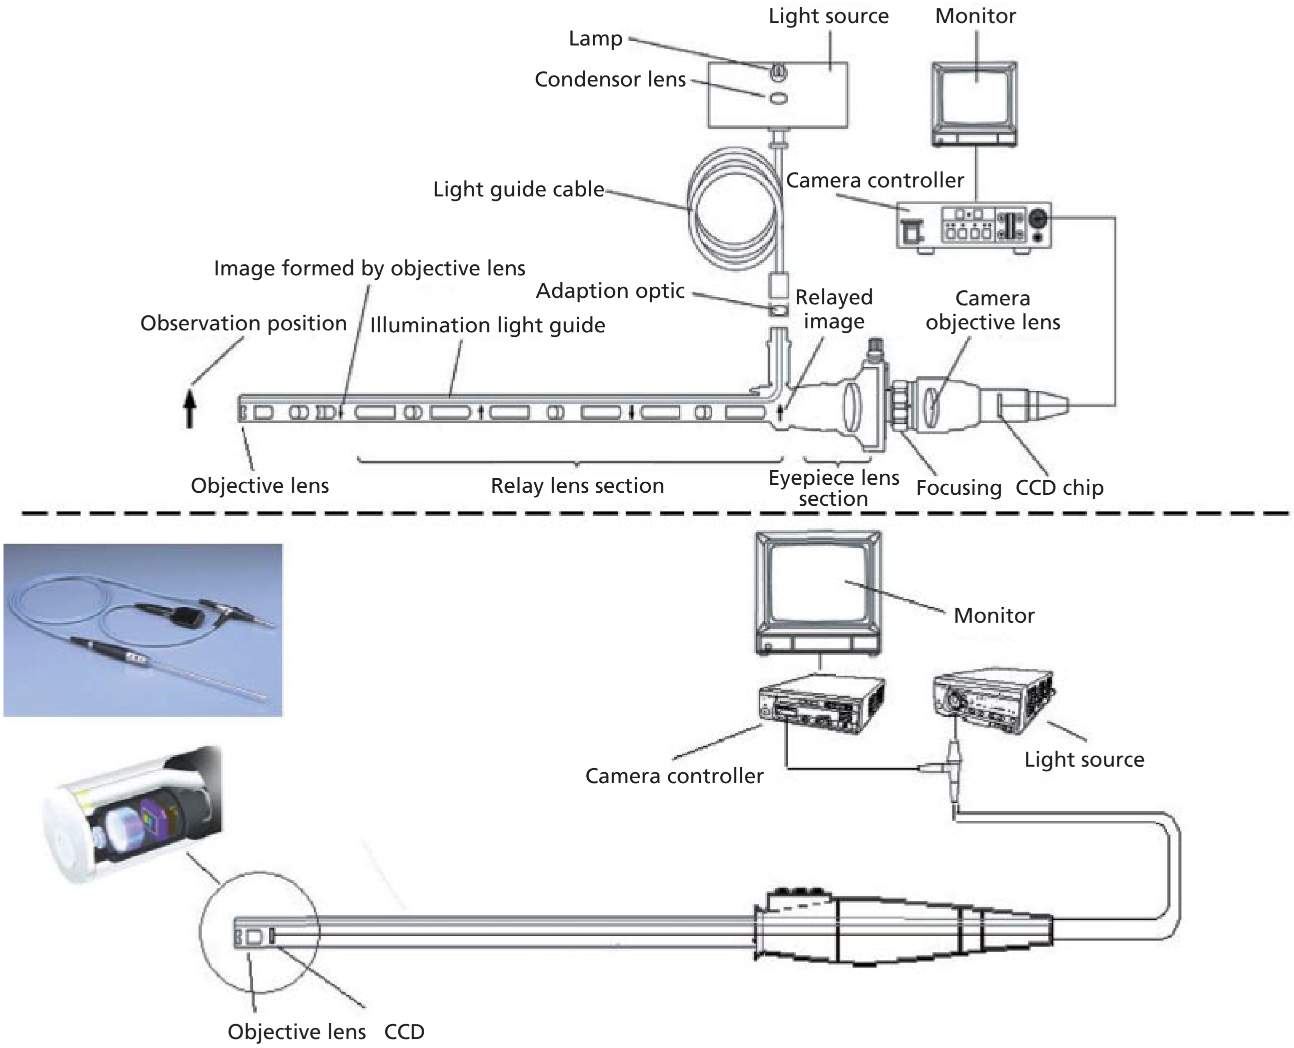

Figure 3.3 Traditional technology (top) compared with electronic transmission videoendoscopes (bottom). CCD, charged coupled device (photograph reproduced courtesy of Olympus ACMI Business Group, a division of Gyrus ACMI, LP, Southborough, MA, USA).

endoscope (Figure 3.3). Instead of relaying optical images from the objective lens at the distal end of the scope to a camera attached to the eyepiece, the image is immediately captured by the CCD chip, digitized, and converted into electrical signals for transmission. This endoscope design has fewer interfaces, allowing the digital information to be directly transmitted to an image display unit with minimal image loss, interference, and distortion [15, 16]. The creation of true videoendoscopes especially benefits the flexible ureteroscope and cystoscope. As internal optics are not required in the long and flexible shafts of these instruments, durable deflection mechanisms can be utilized to improve the durability of flexible endoscopes [17, 18]. With no need to attach a camera head to the eyepiece of the scope, the videoscope cable can be secured to the light cord for attachment to the video system, providing a lighter and more convenient set-up. This technology has been incorporated into larger, rigid endoscopes (laparoscopes), as well as rigid and flexible cystoscopes and ureteroscopes [19–21]. This innovation is due to recent technologic advances which have allowed miniaturization of CCD chips. Such an integrated digital videoendoscope can be expected to replace many endourologic endoscopes in the near future.

Another development in digital camera technology includes the use of a single monochrome CCD chip with alternating red, green, and blue illumination to form a color image, rather than using three chips with three separate color filters. This design reduces the space requirements and takes advantage of established high-resolution monochrome CCD chip technology [15]. This design has been utilized in a digital video cystoscope (Olympus ACMI Business Group, a division of Gyrus

Figure 3.4 Digital ureteroscope with "chip on a stick" technology. Olympus URF-V flexible ureteroscope. (reproduced courtesy of Olympus ACMI Business Group, a division of Gyrus ACMI, Southborough, MA, USA).

ACMI, Southborough, MA, USA). More recently, this technology has been applied to flexible ureteroscopy. The Olympus URF-V flexible ureteroscope (Olympus ACMI Business Group) uses a CCD camera at its distal tip (Figure 3.4). This ureteroscope has demonstrated improved optics, including higher resolution, greater illumination, and improved color reproduction, when compared to a fiberoptic flexible ureteroscope [22]. In addition, the image is 5.3 times larger than that provided by a fiberoptic ureteroscope [22]. The URF-V has demonstrated improved subjective visibility and flexion in clinical use as well [23]. Such technology is currently being incorporated into digital laparoscopes.

Other techniques under development for image resolution enhancement include the use of complementary metal oxide semiconductor (CMOS) technology to replace the CCD sensors [24]. Both CMOS and CCD imagers are manufactured in a silicon foundry; and the equipment used is similar. But alternative manufacturing processes and device architectures make the imagers quite different in both capability and performance. It is technically feasible but not economic to use a CCD processor to integrate other camera functions, like the clock driver and signal processing. These are normally implemented into secondary chips. Thus, most CCD cameras comprise several chips. On the other hand, one of the major benefits of CMOS cameras over the CCD design lies in the high level of product integration that can be achieved through virtually all of the electronic camera functions on the same chips. Typically, a CMOS processor allows lower power usage and lower system cost. This technology is currently being used for digital ureteroscopy [25]. The Gyrus ACMI Invisio DUR-D digital flexible ureteroscope (Olympus ACMI Business Group) uses a CMOS imaging sensor coupled to a prism at its distal tip. The image is transmitted via nine wires through the scope to the camera control unit. The ureteroscope also has two light emitting diodes (LEDs) at its tip. This digital ureteroscope was shown to have superior resolution and contrast discrimination to standard fiberoptic ureteroscopes [26]. Another of its advantage is that it weighs nearly 50% less than a fiberoptic ureteroscope with the camera and light cord attached [27].

Video light sources

In addition to a CCD camera, a high intensity light source, usually either halogen or xenon, should be utilized for appropriate illumination. Certain light sources have an automatic light-sensing feature which quickly adjusts the light output as required by the camera. This automatic light adjustment feature is particularly helpful during endoscopic procedures, as the endoscope may be rapidly moved throughout the abdominal cavity or urinary tract, causing areas of too much or too little illumination. Light intensity will be automatically altered to maintain a preselected illumination level. As noted previously, some camera systems are equipped with an "automatic iris" system which will electronically increase or decrease the "aperture" of the camera shutter. If the camera system is equipped with such a light-sensing feature, there is no need for an automatic light-adjusting light source. Newer CCD- or image sensor-based endoscopic cameras feature electronic exposure. This system varies the effective exposure period (i.e. light gathering time) of the CCD as the live image is captured. Typical CCD exposure periods range from approximately 1/60 of a second to 1/10 000 of a second under very bright conditions. This electronic process can be used to maintain the brightness in the image. When the image brightness must be reduced to improve picture clarity, the image signal exposure period can be reduced electronically instead of adjusting the iris of the light source.

Shadows play an important role in depth perception and spatial orientation. Studies have demonstrated that endoscopic task performance significantly improves with video systems that provide proper illumination and appropriate shadows in the operative field [28]. Many of the current endoscopes employ a simple frontal illumination technique that produces an optically flat and shadowless image with resultant poor contrast. Newer illumination and imaging technologies provide shadow inducing systems using a single- or multi-point illumination system. One of these techniques employs the use of two independent illumination fiber bundles, with one fiber bundle ending at the front lens, as designed in conventional endoscopes, and the other fiber bundle ending behind the tip of endoscope. This configuration results in an improved image with better contrast due to shadow formation. Spatial orientation and perception between anatomic structures are considerably enhanced [24].

Video documentation systems

The ability to make permanent copies of video-monitored cases is useful in documenting these procedures from both a medicolegal viewpoint and as part of the patient's permanent medical record [29]. Hard copy pictures or video recordings of some endoscopic procedures may also be an important adjunct during follow-up, if repeat endoscopic procedures are necessary. For example, stored video images of a patient with multiple superficial bladder tumors will allow the urologist the opportunity to review "before" and "after" images after treatment has been completed.

The ability to store sequential video images on an optical disc is another advantage of utilizing video during endoscopy. It can provide the referring physician with prompt and detailed information regarding the surgical care of an individual patient. Video disks and hard copy technology now allow the presentation of patient data, graphic displays, and video images on standard photographs which can be placed in a patient's medical record. Enhanced digital printing technology is also available which allows actual video images to be printed directly into an operative report.

One such system allows multiple video images to be stored during the endoscopic procedure. At the completion of the case, various video images can be selected and are integrated directly into a dictated operative report. Such a report format proves invaluable for medicolegal purposes, as well as for dramatic documentation for the referring physician.

In addition, digitalization of video images also permits specific endoscopic procedures to be brought "online" into a computer database system and further facilitates the use of a "paperless" medical record. Once the various video images are on the computer network, they can be recalled from any workstation in the hospital that is linked to the network. Moreover, computer-manipulation (image processing) can be used to further enhance the video images [30].

Hard copy pictures

A hard copy printer generates an immediate, high quality color photograph which can be used for documentation [31]. One, four, or nine separate pictures can be stored in the printer's memory and then reproduced on the same hard copy, which allows final results to be documented for the patient or referring physician or for use in the patient's permanent record. Some of these hard copy printers also contain character-generating capabilities which allow text to be added to the video images.

Digital image storage

Surgical video systems have integrated digital image capture systems, allowing immediate capturing of still images from endoscopic procedures[18] (Figure 3.5). Alternatively, a less expensive digital still image capture adapter can be connected to endoscopic camera systems [9]. Digital still images can usually be recorded in Joint Photographic Experts Group (JPEG), tagged image file format (TIFF), or bitmap (BMP) formats. These digital images can be edited and optimized on the computer using various graphic software packages. Incorporating medical images into the patient's record, as well as creating an image library, can enhance urologic practice [32, 33]. The quality of the digital image required depends upon its purpose. Low-resolution images, in the range of 1–2 MP, can be used for email attachments or PowerPoint presentations. A higher quality image (from 3–4 MP) is more useful if a printed image is required. In cases where storage is not an issue, the image should be obtained at its highest resolution, thereby allowing for future image manipulation.

Video recording

Previously, the majority of video recordings during endoscopic procedures were performed with conven-

Figure 3.5 Still images and short video clips (depending on resolution) can be captured on a digital card. Direct digital video stream can be captured on a computer, digital camcorder, or digital recorder via an IEEE 1394 fire wire connector on the back panel. tional analog VHS or S-VHS formats, which could be digitally converted. The introduction of digital video recording devices now allows video footage to be recorded directly into a digital format [i.e. Digital Video (DV), Moving Picture Experts Group (MPEG), and Audio Video Interleaved (AVI)] (Figure 3.6). Newer technology allows for storage of video and still images directly onto a portable Universal Serial Bus (USB) drive (Figure 3.7). This allows for easier storage and transfer of video images. A unique feature of this device is it allows the surgeon to confirm what is being recorded by viewing a small liquid crystal display (LCD) screen on the device. These video-capturing systems can be either part of an expensive commercial integrated video system, DV camera, DVD recorder, or a low cost personal computer with digital video capture card [34]. Digital video editing may be performed on a personal computer using various editing programs (e.g. Adobe Premiere, Movie Maker, Corell).

Smaller still digital images can be stored on different digital storage media (SmartMedia, Compact Flash, Secure Digital, Multi Media card, and Memory Stick). For larger files, especially video clips, Zip Disk (up to 750 MB), CD-ROM (up to 700 MB), and lately DVD (up to 17 GB) can be utilized. In addition, portable external hard drives are currently available with up to 1 TB. However, data storage for a large number of images can still be an issue. Picture archiving and communication systems (PACSs) are currently being utilized in an important role to store and allow easy access to medical images [35–37].

Image transmission

As we advance into the age of digital video imaging, images that have been "captured" can be immediately displayed, stored, printed, or transmitted to various locations throughout the hospital or off-site. While video images can be transmitted over standard telephone lines, the narrow bandwidth of standard coaxial copper cable limits the quality of transmitted video images. Moreover, it is often difficult to transmit full motion video over standard telephone lines. Currently, three newer modes of image transmission are being utilized in the communications industry and can therefore also be applied for the transmission of video images throughout the operating room, hospital, or to distant sites.

Fiberoptic cable

Optical fiber has rapidly replaced coaxial copper cable as the preferred mode of data transmission. Optical fiber offers significant advantages over coaxial cable as it can

carry significantly more information in a small amount of space. For example, one fiberoptic fiber can carry upwards of 1.7 GB/s. This rate is thousands of times faster than data transmitted over standard coaxial cable. Moreover, optical fiber has a lower attenuation than coaxial cable and is not subject to electromagnetic interference. The major advantage of optical fiber is that large amounts of digitized information (video, audio, data, etc) can be rapidly transmitted [29]. This increased speed of transmission is especially important when dealing with the large amount of digital information contained in video images.

Wireless local area network

Recently, wireless local area networks (wireless LAN or "WiFi") have been introduced in the healthcare setting. These networks allow transmission of data and images to laptop and handheld computers throughout the patient care environment, and often form the final link between a wired hospital network and the mobile user. The current standard, 802.11n, is set by the Institute of Electrical and Electronic Engineers (IEEE), and provides for data transmission at speeds up to 150 MB/s. At these transmission rates, digital still and video image transmission becomes reasonable [38].

The advantages of a wireless network are the ability to communicate with mobile users, ease of installation without the need for construction of a wired network, and flexibility for future technologic advances. Disadvantages can include initial set-up costs and the battery requirements of mobile workstations. Concerns have been expressed about interference of wireless devices with medical devices, but interference only occurs with a few devices and only when the medical device is within 10 cm of the LAN transmitter [39]. Wireless networks have been successfully used to transmit radiologic images for interpretation, as well as a live broadcast of laparoscopic surgery to handheld computers for instructional purposes [40–42].

Satellite communications

The advent of satellite communications has also allowed the transmission of digitized video images to remote areas that are not linked by coaxial cable or fiberoptic conduit. Satellite communications currently allow the performance of teleconferencing and telemedicine, where voice and video images can be almost instantaneously transmitted to remote sites, to allow interactive communication. Currently, it is believed that a combination of fiberoptic cable and satellite transmission systems may globally link distant operating rooms to major medical centers, thereby greatly facilitating performance of advanced endoscopic procedures. An experienced surgeon can assist or perform complex endoscopic procedures at the remote site (telepresence surgery).

Figure 3.8 Video carts contain video camera electronics, light source, and various recording devices (reproduced courtesy of Olympus America Inc.).

Video system set-up

Video cart

An essential part of any video system should be the video cart. This cart is an integral component for the entire system, which allows easy transport of the video documentation system from one surgical suite to another (Figure 3.8). The video cart should have room to hold the video camera electronics, the light source, and various recording devices such as a hard copy printer or DVD recorder. Moreover, some video carts will also have room to hold the laparoscopic insufflator as well as electrocautery units. The cart needs to be adequately secured during storage to prevent equipment loss, and to have the capability to hold CO_2 tanks which will be needed during laparoscopic procedures.

Video set-up

Traditionally, our standard operating room set-up places the video cart, which contains a video camera and recorder, television monitor, and xenon light source, directly across from the operating surgeon. In addition, a second high resolution video monitor is placed on the

other side of the table to be used by the assistants. If only one video monitor is available, it should be placed directly at the end of the operating table. All endoscopic procedures in our endoscopy suite and operating rooms are performed entirely off the video monitor(s).

With the advent of more current operating room designs, the fundamental differences between open and endoscopic or laparoscopic surgery have been recognized. Whereas in the past endoscopists and laparoscopists relied upon mobile carts traveling from room to room, today specialized rooms provide dedicated carbon dioxide lines, preventing the need to change tanks in mid-operation. Another issue relating to suboptimal operating room design is the effect of imperfect ergonomics on surgeon comfort from a musculoskeletal standpoint. Many recent studies have demonstrated significant stressors to the surgeon induced by laparoscopy, many of which are related to monitor placement, camera holding, trocar placement, and table position and height [43–46]. Operating room enhancements, such as ceiling-mounted monitors and designs focused on the endoscopic and laparoscopic surgeons, allow for versatility in the ergonomics surrounding minimally invasive urologic procedures (Figure 3.9). Whether or not these specially designed operating rooms improve upon musculoskeletal complications in surgeons has yet to be determined, but some studies indicate that this is the case and that overall operating room efficiency is improved as well [47, 48]. A novel addition to the operating room of the future may incorporate high-resolution binocular face-mounted devices, such as have been explored at the bench level, thus providing less surgeon neck/back strain and improved visualization and satisfaction compared to conventional standard video monitors [49].

Future directions of endoscopic video systems

As previously noted, significant advances have been made in the development of video imaging technology for minimally invasive surgical procedures. A major limitation of current video systems, however, continues to be the two-dimensional images provided to the surgeon. Although the image quality itself is quite satisfactory, the lack of depth perception may impair delicate dissection or suturing during minimally invasive procedures, as motion parallax and other indirect evidence of depth is relied upon to judge the correct spatial relationship of the objects in the operating field. At times, the tissues have to be actually touched in order to gauge depth, thereby significantly reducing the speed and precision at which minimally invasive surgical procedures can be performed.

Moreover, as advanced reconstructive minimally invasive surgical procedures are developed, some training opportunities become limited. This lack of "routine" cases makes it often difficult for the medical student, house officer, and practicing physician to become familiar with more complex minimally invasive surgical maneuvers. Therefore, a way to simulate such complex procedures would be beneficial to aid in the training of the endoscopic surgeon.

Three-dimensional (3D) video systems as well as high-definition television have been recently introduced to significantly improve visualization during minimally invasive surgical procedures. In addition, virtual reality techniques have been developed, which allow enhanced image processing of videoendoscopic procedures as well as the development of surgical simulations to aid in training of complex surgical maneuvers. The following sections will review these enhanced imaging technologies for endoscopic surgery.

3D Video imaging

3D video imaging enhances the ability to perform delicate endoscopic maneuvers, such as dissection or precise suturing [50]. Moreover, those who are observing have a better understanding of the surgical anatomy because of the 3D image.

Principles of 3D stereoendoscopy

In normal human vision, depth perception is a factor taken for granted. Normally, the eyes will accommodate and converge in such a way that there is intersection of the visual axes of both eyes. This intersection is known as the point of fixation. When viewed by both eyes, lateral disparity causes the viewed object to be projected in slightly different orientations on the retina of the right and left eyes. The human brain interprets this disparity on a small region of the retinal fovea (called the Panum's region) as depth information. The brain then fuses these images to give the perception of depth, and this effect is called stereopsis [51].

Accommodation is the ability of the human eyes to clearly visualize objects which are both near and farther away. The eyes converge, and the lens increases its dioptic strength so that the object is brought into sharp focus on the retina. The nearest an object can be to the eye and still be in focus is called the near point, while the farthest it can still be in focus is called the far point. The region of depth is the area between the near and far points. This ability to accommodate is preserved when viewing objects with a 3D video system.

As noted, when viewing a particular object with binocular vision, it is normally perceived in three dimensions. However, if one eye is closed, a "flattening" of the image might be noted. Owing to the capability of the "image center" within the brain to capture and recall

Figure 3.9 Current (future) endoscopic/laparoscopic operating room (OR). (A) Ceiling-mounted flat panel monitors. Builtin endoscopy table with adequate room for laparoscopic applications. (B) Touch panel control allowing for routing of different source images on different monitors. Wall plug in for C-arm integration with room monitors. (C) Ceiling-mounted camera for external footage (reproduced courtesy of Stryker).

images, the viewed object may appear with somewhat limited depth (i.e. 2.5D). This ability to visually process two-dimensional (2D) flat images off a standard video screen and view them in a partial 3D manner may be a significant factor in the ability of experienced endoscopic surgeons to adequately perform endoscopic surgical tasks. This innate ability to perceive standard flat video images in three dimensions is significantly reduced when the surgeon is confronted with a scene which has not been viewed before. Therefore, the introduction of 3D video systems should facilitate the performance of endoscopic surgical procedures, especially those which require intricate dissection or reconstructive techniques.

To mimic normal 3D vision, a 3D video system must therefore convey separate off-set images to each eye. The figure is captured in a slightly different orientation by the stereoendoscope and, after image processing by the brain, it appears as a 3D object. Any 3D video system must therefore incorporate the principles of stereopsis [51, 52]. One potential limiting factor of 3D endoscopic systems is that the normal interpupillary distance for human vision is approximately 60 mm, while the maximum separation of two objective lenses in a standard 10-mm endoscope is approximately 8 mm. Various endoscopic designs, however, have accounted for this disparity, still allowing for adequate capture and display of 3D images.

Stereoendoscopic image processing

Most of the 3D stereoendoscopic video systems currently available have four basic principles of stereoendoscopic image processing in common: image capture, conversion of 60–120-Hz images, presentation of left and right images on a single monitor; and separation of the left and right eye images [53]. The following sections will describe in more detail current stereoendoscopic equipment utilized for 3D endoscopic surgery.

Stereolaparoscope

Stereolaparoscopes are of two basic designs: a two-lens optical system or a single optical channel. The dual-lens systems individually capture slightly different images of the operating field, much like the right and left eye will capture slightly different views of a single image. The parallel optical channels then present the separate images to the left and right eye camera systems.

In contrast, the single optical channel design captures the image with a single objective lens at the distal end of the endoscope. At the proximal end of the endoscope, adjacent to the stereo camera, the image is split into separate left and right eye images. One advantage of this single optical channel design may be higher resolution and more light for the 3D video image than presented by the smaller two optical systems contained in the dual optical channel endoscopes.

Image splitter

The single-channel 3D video systems utilize a device to split the images captured by the left and right half of the single-lens endoscopes. In some systems, the image splitter is incorporated into the proximal end of the single-channel stereoendoscope [54].

Stereo camera

Most 3D video systems contain a stereo camera head which incorporates two separate CCD image sensors (usually half-inch CCD chips) that capture the images from the stereolaparoscope. These images from the stereolaparoscope are viewed by the left and right eye cameras, just as two separate images are presented to the left and right eyes during normal binocular vision.

3D image processing

Most 3D video systems contain a 3D conversion unit which processes the images obtained from the left and right eye cameras. These conversion systems allow the left and right eye images to be alternately synchronized on a single stereoscopic monitor at 120 Hz (60 Hz for each eye). If the images are presented slower than 120 Hz, substantial "flicker" on the video monitor may be noticed. Moreover, slower speeds of video display may also cause vertigo.

The 3D video conversion systems will allow viewing of live 3D procedures, and recording of surgical cases in three dimensions with subsequent playback of these cases in three dimensions. While initial 3D video systems recorded left and right eye images on separate video recorders, current systems can capture both on a single video. The left and right eye images are stored on a single "video frame," which greatly simplifies the recording, playback, and editing of 3D endoscopic images. The image processing unit and standard 3D video monitor are both necessary to view the previously recorded endoscopic images.

3D display

The 3D conversion system will sequentially display the left and right eye images on the 120-Hz 3D video monitor. However, in order to view the left and right eye images on a single monitor, the images must be separated. One method involves "active" LCD shutter glasses. These glasses are synchronized by an infrared emitter which is located on top of the video monitor. As

the left eye image is projected on the video screen, the emitter will control the shutter glasses so that the right eye is closed and the left eye is open. Alternatively, when the right eye is open, the left side of the LCD glasses is blackened and the right eye image appears on the video screen. The advantage of this active system is that more light is projected to each eye and therefore the 3D image appears brighter. However, the active LCD shutter glasses require a battery, and are somewhat heavy and quite expensive (approximately US$1000).

Alternatively, "passive" polarized glasses may be worn to view the left and right eye images from the single video monitor [54]. This type of system requires a special polarizing filter on the video screen which will "rotate" the left and right eye images in different orientations, thereby allowing simultaneous viewing of the left and right images. The passive polarized glasses have the advantages of significantly cheaper cost than the active LCD shutter glasses and are more comfortable to wear, but the polarizing glasses present a slightly darker 3D image than the active glasses.

An alternative to dual projection is the presentation of the two images independently to the left and right eye, much like looking through field binoculars. The images can be displayed on small screens set at the focal distance for the surgeon and mounted on an ergonomic headset [55]. This technology is currently available as part of the DaVinci robotic system [56].

Recording and projection of 3D video images

Early 3D video systems required two separate recorders to capture the left and right eye images. However, the majority of systems now currently utilize a 3D conversion system that will alternatively store the left and right eye images on a single disk. This system design allows efficient capture of 3D video footage for play back at a later time.

There are also 3D video projectors available which will alternatively display left and right eye images on a large video screen. (Such 3D video projectors are ideal for large group demonstrations and for educational purposes. As with separation of images during viewing on a 3D video monitor, the 3D video projector can utilize active LCD shutter glasses or a passive polarized lens systems.

Advantages and limitations of 3D videoendoscopy

The increased depth of field afforded by 3D endoscopic video systems facilitates intricate minimally invasive surgical procedures [57, 58]. Addition of a third dimension allows better recognition of tissue layers and may facilitate complex maneuvers, such as laparoscopic suturing or knot tying [59]. Indeed, skill tests performed assessing laparoscopic suturing and knot tying have demonstrated a 25% increase in speed and accuracy of these laparoscopic tasks when utilizing a 3D video system as compared to a standard 2D endoscopic video system [60]. Some investigations claim that 3D video systems only facilitate surgical tasks in inexperienced laparoscopic surgeons. It appears that the reduction in time required to perform various minimally invasive surgical procedures may not be as dramatic in those individuals who have a large amount of experience with standard 2D video systems during endoscopic surgery [55]. Some studies suggest that a higher resolution video system might be more advantageous than having 3D endoscopic imaging [61–63]. The major current use of 3D imaging systems is during laparoscopic, robotic surgical procedures, to allow for true stereoscopic imaging [64–66].

Late model 3D videoendoscopic systems compared with initial 3D components provide greatly improved 3D viewing of minimally invasive surgical procedures. Yet, they still provide reduced resolution and lower-light images as compared to standard single- or three-chip 2D video cameras. The decrease in image brightness and resolution is due to the fact that most 3D video systems use two optical channels that are significantly smaller than a single-lens system in a standard 10-mm laparoscope. Moreover, since most 3D video systems incorporate two separate camera systems, the camera head is significantly larger than a single-camera system and, therefore, more cumbersome to work with during minimally invasive surgical procedures.

Cost continues to be a limitation of 3D videoendoscopy. Most 3D video systems are two to three times more expensive than standard 2D endoscopic video cameras. While more costly, the enhanced depth perception produced by 3D endoscopes has been demonstrated to improve the performance of minimally invasive surgical procedures [67, 68]. 3D imaging also facilitates the training of minimally invasive surgery and may lessen the learning curve of these technically demanding procedures [69]. It is anticipated that 3D video imaging will significantly improve the performance of current endoscopic procedures as well as facilitate the development of more advanced, minimally invasive surgical techniques [50].

High-definition television

The development of high quality image display systems has become essential during endoscopic surgery. Previous studies have demonstrated that the inherent optical quality of most endoscopes and CCD cameras exceeds the display resolution of standard television [70]. With the limited resolution of current analog NTSC, phase alternation line (PAL), and sequential color and

memory (SECAM) monitors, there is a demand for higher resolution image display systems. One such digital display system is HDTV. The most common HDTV formats used in the USA are 1080p and 1080i. The "p" represents progressive scanning, meaning that each scan includes every line for a complete picture, while the "i" signifies interlaced scanning with each scan including alternate lines for half a picture. These scan rates translate into a frame rate of up to 240 frames/s, eight times that of conventional television monitors. HDTV offers greatly enhanced picture quality with improved image resolution. HDTV pixel numbers range from 1 to 2 million, compared to NTSC, PAL, or SECAM's range of 300 000 to 1 million. The other significant feature of the HDTV format is its wider aspect ratio (the width-to-height ratio of the screen) of 16:9 as compared with NTSC, PAL, and SECAM screens, which have an aspect ratio of 4:3. Studies have suggested that the wider aspect ratio provides more information for the viewer, thereby enhancing both diagnostic and therapeutic interventions [9, 63].

High-definition digital laparoscopes are currently available for use and offer many significant advantages over standard definition (SD) laparoscopes. Surgeons have subjectively rated HD images superior to SD images during laparoscopy in both the laboratory and clinical setting [71]. One recent study performed an objective comparison of performance characteristics between the Olympus HD 10-mm laparoscope (Olympus ACMI Business Group) and the Olympus SD 10-mm zero-degree laparoscope [72]. The HD laparoscope had improved resolution, decreased distortion, greater depth of field, and improved lumenis flux when compared to the SD laparoscope. Given the importance of visual cues in performing laparoscopic surgery, these improvements could be of great significance. Laparoscopy performed with an HD camera in combination with an HD monitor can improve the performance of surgical tasks, specifically laparoscopic knot tying, which requires precise depth perception [71].

The future application of high-definition imaging (HDI) technology would improve endoscopic image resolution based on CCD chips. The European standard HDI chip resolution is 2 340 250 pixels, resulting in 1250 horizontal lines. HDI has the advantage of resolution enhancement for image brilliance and the augmentation of secondary depth clues such as shadows. With the use of CMOS technology to replace CCD sensors, image resolution may be further enhanced [24].

The improved resolution and color separation of HDI provides better diagnosis and enhances the effect of secondary spatial cues, leading to easier orientation, particularly if the images are combined with improved illumination. Despite its current high cost, the price of HDTV cameras and monitors will continue to decline as newer HDTV products come onto the consumer market. With further optimization of size and weight of the camera system, HDTV will likely become a standard feature for endoscopic imaging and display during endoscopic and laparoscopic procedures (Figure 3.10).

Virtual reality

Endourologic procedures require specific training to achieve competency. Often, there are reduced training opportunities for residents due to a limited number of clinical cases. Moreover, ethical and cost issues may further limit the use of animal or cadaver models for training purposes [73–75]. While hands-on training using bench models can successfully teach laparoscopic skills, it precludes the ability to vary clinical conditions [76]. Moreover, inanimate simulators lack the realistic feel of living tissue.

Advances in virtual reality (VR) simulation offer a practical tool for urologists to practice various endourologic procedures, from the basic to the most complex, in an inanimate but dynamic, life-like environment without risk to patients or ethical issues. Accurate reproduction of anatomic structures provides a realistic VR surgical simulation. Models should also provide appropriate tactile feedback and spatial cues.

As endoscopic procedures require little in the way of complex anatomic and tactile feedback, one of the earliest simulators in urology was a VR ureteroscopy simulator (Immersion Medical, Gaithersburg, MD, USA) [73, 74, 77]. This simulator allowed urologists to explore the ureter and kidney for pathologic processes, specifically, stones and tumors. However, this early simulator was limited due to lack of true anatomic representation and inadequacy in computer graphics. Advances in computing power, VR graphics, and physical modeling techniques resulted in a new endoscopic simulator (URO Mentor system, Symbionix, Tel Aviv, Israel) [78]. This is a commercially available VR modular endoscopic simulator that provides virtual cystoscopy and ureteroscopy procedures using either rigid or flexible endoscopes. Realtime fluoroscopy with simulation of C-arm control and viewing of fluoroscopic images of injected contrast can also be simultaneously combined with endoscopic procedures. Various endourologic procedures, including cystoscopy, retrograde pyelography, insertion of guidewires, ureteral stenting, ureteroscopy, stone fragmentation, and fragment removal using various tools, can be realistically simulated. Studies have demonstrated that use of this VR simulator resulted in more rapid acquisition of ureteroscopic skills in urologic trainees [79–81] In fact, studies of both laparoscopic and ureteroscopic simulators have demonstrated a significant reduction in the learning curves to perform both routine and complex endoscopic procedures.

Figure 3.10 Current operating room with high-definition television (HDTV) monitors.

Endourologic skills can also be validated using VR simulation [75, 82].

Further advances in computer and software technology have allowed VR simulation to become more realistic for the performance of laparoscopic procedures [83–86]. The LapMentor system (Symbionix) is a VR system for the training of laparoscopic skills and surgical procedures. This system has been validated as a training modality for laparoscopic skills [87]. It has been demonstrated in a randomized, double blinded study to improve basic laparoscopic skills of surgical residents [88]. Training residents with a laparoscopic VR simulator to a certain level of proficiency can decrease intraoperative errors and operating time during their initial live surgical experience, thus reducing the learning curve [89, 90]. Similar to the aviation industry, VR simulation will likely be incorporated into the training, testing, and credentialing of endourologists and laparoscopic surgeons over the next 5–10 years.

Image-guided surgery

Augmented reality (AR) involves the integration of preoperative radiologic imaging with realtime intraoperative surgical views. It allows the surgeon to "see" subsurface information which is inaccessible through ordinary endoscopic imaging. Augmented reality and imaged-guided surgery (IGS) have many potential advantages over conventional endoscopic surgery. AR has the potential to replace the loss of haptic feedback in robotic and laparoscopic surgery by allowing surgeons to see anatomic and spatial relationships which are not obviously apparent through standard or 3D views. In addition, AR and IGS have the potential to predict surgical results [91]. These features have the potential to minimize the loss of healthy tissue while maximizing oncologic efficacy.

Various techniques have been described for the implementation of IGS and AR. Realtime virtual sonography (RVS) has been described, allowing synchronization of preoperative computed tomography (CT) or magnetic resonance (MR) images with intraoperative realtime ultrasound images [92, 93]. The system displays the realtime ultrasound image and the corresponding image of a 3D reconstructed CT or MR image. This technology is especially useful for percutaneous ablative procedures for the kidney or prostate.

Other investigators have reported on the use of AR for laparoscopic partial nephrectomy [93]. They utilized an optical tracking system for their surgical instruments combined with a computer workstation to overlay preoperative 3D reconstructed images onto their surgical view. For laparoscopic partial nephrectomies, the images were displayed with colored zones corresponding with the tumor and various margins. Other techniques have been described for coordinating the preoperative images to the intraoperative view. One system placed navigation in the target organ for better localization and to account for organ movement [94]. This technique has been coined as the "inside-out tracking system." The tracking system was able to overlay images onto the operative field with a 0.5-mm error margin.

AR has also been applied to robotic assisted laparoscopic partial nephrectomy [95]. The system allows overlay of 3D models constructed from preoperative CT scans onto the 3D intraoperative video recordings. The advantage of this system is it does not require external tracking devices. Another model for AR utilized the da Vinci robot system as a single localizer [96]. This system demonstrated decreased removal of benign tissue in an *in vitro* model.

All of these systems currently allow for 3D reconstructed, preoperative images to be displayed onto realtime endoscopic surgical views. The major limitation is accounting for organ motion and deformity. The future of AR and IGS is predictive surgical navigation. Gill and Okimura described a surgical radar and a surgical body gravitational positioning system (GPS) [92]. Surgical radar involves displaying color-coded zones over the realtime image of an intended surgical target. The trajectory of an instrument, e.g. endoscopic scissors, can be used to predict whether the current path of that instrument will violate an undesirable structure, such as a tumor. Surgical body GPS allows for monitoring of realtime organ position. The surgeon can be alerted to how realtime movement of the organ alters the line of excision for an intended target. The aim of this technology is to maximize normal tissue preservation and oncologic efficacy.

Internet and telemedicine

In recent years, telemedicine, defined as the use of electronic information and communication technologies to provide and support healthcare from a distance, has become an important aspect in patient care. Advances in digital imaging, high speed computer connections, and the widespread availability of the Internet have allowed a steady growth of telemedicine within urology [97]. The applications of telemedicine have grown from a simple sharing of information to actual performance of surgeries remotely [98].

Digital still images and streaming video/audio can be transmitted over the Internet using a variety of available modalities, including Integrated Services Digital Network (ISDN) at 128 kB/s, T1 lines at 1.54 MB/s, coaxial cable at up to 6 MB/s, and Asymmetric Digital Subscriber Line (ASDL) at 1–3 MB/s [9, 11, 32]. More recently, video transmission has been described utilizing Digital Video Transfer System (DVTS) software over the Internet [99, 100]. DVTS has been used successfully for realtime video conferencing with data transfer speeds up to 30 MB/s over the Internet and up to 100 MB/s over a LAN [99, 101]. The system described by Huang *et al*. could deliver live video of 720 x 480 pixels at 30 frames/s [99]. The advantages of DVTS are preserved image quality and relatively low cost [99, 101]. In addition, the use of a virtual private network (VPN) router allows for encryption of the images without degradation of the quality [99]. This is important for maintaining patient confidentiality.

Telemedicine is most commonly utilized for educational purposes and for telementoring. It is now routine for endourologic surgeries ranging from ureteroscopy to robotic-assisted laparoscopic cystectomies to be broadcast live at educational meetings. The surgeries are performed remotely around the world and the video and audio are projected live to attendees at these meetings. This is an efficient way to disseminate new techniques to large numbers of practitioners. Transmitting live or prerecorded surgical procedures can be done for smaller video conferencing between institutions [100, 101]. The cost requirements for these live video transmissions have decreased considerably. All that is required is access to the Internet, DVTS software, which can often be obtained for free, a digtial video recorder, and monitors to view the procedures. Another educational application of telemedicine is video journal submissions. Urologic journals are now accepting video submissions for publication. This goes well beyond descriptive text for dispersing new techniques and procedures. These video submissions can not only be viewed online, but they can be downloaded for increased portability.

Telementoring involves realtime guidance and instruction by an experienced surgeon to a less experienced surgeon at a remote location utilizing video and audio connections [102]. Kavoussi and colleagues reported on their initial laboratory experience with telemedicine in 1994 [103, 104]. In 2000 they reported on their clinical experience telementoring laparoscopic surgery in Rome, Italy [105]. During these five laparoscopic cases, a more experienced team in Baltimore, USA, oversaw procedures performed in Rome in real time. They offered advice, provided quality control, and even operated instruments remotely. The cases performed included a laparoscopic nephrectomy. More recently, the group in Baltimore aided in the

performance of a laparoscopic varicocelectomy and a percutaneous nephrolithotomy in Brazil [106]. Images and audio were transmitted utilizing ISDN lines, which provided video rates of 15 frames/s with a signal delay of 700 ms. Newer technology utilizing DVTS can transmit video at 30 frames/s with a signal delay of 280 ms [100]. Agarwal *et al*. recently reported on the novel use of the RemotePresence-7 (InTouch Health, Sunnyvale, CA, USA) robot as a remote intraoperative consultant [107]. This robot has two digital cameras, an audio microphone, and is mobile. It can be operated remotely over a broadband Internet connection using a laptop and a remote control. In addition to being able to view the entire operating room, it also has a video input which provides a direct connection with a videoendoscope, allowing the remote physician to view directly the images seen by the operating team. The cost of the robot is approximately $150 000, which can be prohibitive.

What does the future hold? Sterbis *et al*. likely provided us with a glimpse of the future with their recent publication describing telerobotic laparoscopic radical nephrectomies in a porcine model [98]. The animals and robot were located in Sunnyvale, CA, USA and the remote surgeons were either located in Cincinnati, OH, USA or Denver, CO, USA. A da Vinci console was located at both the local and remote site. The remote surgeons controlled two of the three robotic arms and a local surgeon controlled the remaining arm. The video and robotic signals were transmitted over the Internet using nondedicated T1 lines. Commercial video coding/decoding systems (CODEC) were used at both sites to code and decode the information. There was a time delay between 450 and 900 ms and difficulty with visualization in one procedure. Despite these limitations, all four procedures were successfully performed. With continued advancement of technology, remote off-site, real-time telesurgery will become a reality.

Conclusions

The application of video technology to endoscopic procedures provides several advantages in both the teaching and private practice settings not previously available to the urologist. Improved magnification and image quality facilitates performance of the procedure by the surgeon, as well as coordination of the assistants and ancillary personnel to provide a smoother, safer, and potentially shorter operation. Video monitoring facilitates teaching both during and after the procedure, as well as providing preoperative patient education. Video accessories provide immediate documentation for the patient's medical record, for use by the referring physician, or for the patient's own interest. Additionally, video and hard copy documentation provides an invaluable teaching aid for patients and medical personnel. Moreover, videoendoscopic procedures also increase the safety of the procedure for the operating urologist.

As newer technologies, such as HDTV and 3D videoendoscopy, become more widespread, an increasing number of videoendoscopic procedures will be performed. The dissemination of the surgical skills needed to perform these surgical procedures is becoming increasingly important. Technologies such as VR simulation and telementoring will become commonplace in the near future for the training of future urologists. These technologies allow for more rapid acquisition of skills necessary to perform complex endourologic and laparoscopic procedures in a safe environment with reduced risks of adverse events for patients. Future technologies such as IGS should only further improve the safety and efficacy of videoendoscopic procedures. With the advent of new technology for video imaging and documentation, patient care provided by the endourologist and minimally invasive surgeon should rapidly improve.

CHAPTER 4

Preoperative Antibiotics and Prevention of Sepsis in Genitourinary Surgery

Jorge Gutierrez-Aceves, Oscar Negrete-Pulido & Pedro Avila-Herrera

"Dr. Juan I. Menchaca" Hospital, University of Guadalajara, Guadalajara, Jalisco, Mexico

Introduction

Septic complications in urologic surgery constitute one of the most feared and life-threatening situations in current urologic practice In this chapter we will describe the importance of correct preoperative work-up, including adequate antibiotic prophylaxis and intraoperative measures to prevent the development of infectious adverse events and sepsis, as well as the identification of early postoperative events that could lead to sepsis in specific conditions, in order to achieve a prompt diagnosis and reduce morbidity and mortality.

Urinary tract infections (UTIs) and urolithiasis head the list of urologic healthcare cost in the USA [1]. In an Internet-based study conducted by the European Urologic Association (EAU) in 194 different European and Asiatic urology departments, nosocomial UTIss (NUTIs) accounted for 11% of healthcare-associated infections. The most common presentation was asymptomatic bacteriuria in 29%, followed by cystitis in 26% and pyelonephritis in 21%. Twelve percent of all cases presented as urosepsis. Among those patients with NUTIs, almost 80% had a prior history of urologic surgery; endourologic procedures in 50%, open or laparoscopic surgery in 45%, and prostate biopsies in 5% [2]. These data suggest that preventive measures, such as a strict preoperative evaluation and correct antibiotic prophylaxis in surgical patients, must be improved.

The prophylactic use of antibiotics can reduce the risk of surgically-related infection. Recently both the EUA and American Urological Association (AUA) published guidelines and recommendations for best practice in antibiotic prophylaxis in urologic surgery [3–5]. These guidelines are extremely helpful to standardize the administration of antibiotics prior to surgery. However, local practice should be based on or adjusted according to local or even hospital microbiologic patterns and requirements, so it is crucial that each center and department reviews regularly its infection patterns and antibiotic resistance.

There is no uniformity in the literature in the definition of infection versus sepsis, which may account for the wide range of incidences reported. After any diagnostic or therapeutic urologic procedure, UTIs can be present as a simple bacteriuria with limited clinical symptoms or they can result in severe sepsis or even septic shock. It is difficult to predict in which patient a serious complication will develop, but several publications describe potential risk factors that can contribute to this scenario. It is crucial to recognize patients at risk of complications with a complete preoperative evaluation in order that there is a prompt diagnosis and proper treatment in the event of a postoperative infectious complication.

Pathogenesis of urosepsis

Urosepsis is defined as a sepsis caused by UTI; this occurs in 7–25% of all septic cases [6]. An infectious complication is triggered during urologic surgery when urinary bacteria and their products enter the bloodstream via vascular, lymphatic, or urothelial disruption. Manipulation of infected urine or infection stones with an increase in pressure mainly in the collecting system causes an intense liberation of bacteria and endotoxins via direct absorption, pielovenous–lymphatic

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

or pielotubular backflow, and forniceal rupture, and these events then trigger a systemic inflammatory response [7].

There is a neurohumoral generalized pro- and anti-inflammatory response. This begins with cellular activation of monocytes, macrophages, and neutrophils that interact with endothelial cells through numerous pathogen recognition receptors [8]. A further host response includes the mobilization of plasma substances, such as tumor necrosis factor (TNF), interleukins (ILs), caspases, proteases, leukotrienes, kinins, reactive oxygen species, nitric oxide, arachidonic acid, platelet activating factor, and eicosanoids. TNF-α and IL-1 are the most important proinflammatory cytokines and exhibit similar biologic properties. They influence the temperature regulatory centers in the hypothalamus, resulting in fever. They also have an effect on the formation reticularis in the brain stem, which renders the patient somnolent and comatose. Release of adrenocorticotropic hormone (ACTH) in the pituitary gland is increased, which stimulates the adrenal gland. These factors also stimulate hematopoietic growth factors, which leads to the formation of new neutrophils and the release of stored ones. The neutrophils are additionally activated and produce bactericidal substances, such as proteases and oxygen radicals. B and T lymphocytes are stimulated for the synthesis of antibodies and cellular immune reaction. In the continuing septic process however, apoptosis of B cells, CD-4 helper cells, and follicular dendritic cells causes an anti-inflammatory immune suppression, called transient immune paralysis [9].

Activation of the complement and coagulation cascades further amplifies this chain of events. There is microvascular injury, thrombosis, and loss of endothelial integrity (capillary leak), resulting in tissue ischemia. This diffuse endothelial disruption is responsible for the multiple organ dysfunction and global tissue hypoxia that accompany severe sepsis/septic shock [10].

Bacteriology of urinary infections and sepsis

The pathogens associated with UTIs and urosepsis have not varied greatly over the last decades [11, 12], and concern centers around the considerable changes in resistance patterns. A continuous assessment of local patterns is important in order to establish the most appropriate antibiotic regimens to prevent infectious complications most efficaciously.

Escherichia coli remains the single most common microorganism to cause urinary infection. This is followed by *Klebsiella* and *Proteus* spp., frequently associated with stone disease. Furthermore, the increasing presence of Gram positive bacteria such as *Enterococcus* and *Staphylococcus* should be noted.

DasGupta *et al*. reported that 40% of urology inpatients had Gram positive organisms, *Enterococcus* accounting for 27% [13]. Several reports have shown that other organisms have increased not only their incidence, but also their resistance to antibiotics commonly used in urology, including trimethoprim, quinolones, cephalosporins, and aminoglucosides, such as gentamicin; this is the case for *Pseudomonas aeurginosa, methicillin-resistant Staphylococcus aureus* [14], *Serratia* spp., and *Clostridium difficile.* The resistance of *Pseudomona* to quinolones is reported in up to 20% of urology inpatients, with *multiresistant Pseudomona* outbreaks encountered in endourologic units [15]. Kashanian *et al*. [16] recently reported in a retrospective analysis 25% resistance of *E. coli* to ciprofloxacin. This rise in resistance of urinary pathogens towards quinolones has been reported worldwide and might be the consequence of its overuse due to its efficacy in treating other infections and uncomplicated UTIs, as well as its misuse as prophylaxis in some urologic diagnostic procedures.

General measures of sepsis prevention in genitourinary surgical patients

In recent years, the incidence of sepsis has increased, but the associated mortality has decreased, suggesting improved management of patients [17]. Besides correct management, the role of prevention is of great importance and it is imperative to identify preoperative risk factors, apply adequate prophylaxis, and try to minimize intraoperative risks, in order to reduce the incidence of septic episodes or allow early recognition of the features that can lead to one.

The EAU in its Guidelines on Urological Infections recommends the following basic preventive measures of proven efficacy in any urologic patient undergoing surgery [5]:

- Isolation of all patients infected with multiresistant organisms to avoid cross-infection.
- Prudent use of antimicrobial agents, both in prophylaxis and in treatment of established infections, to avoid selection of resistant strains. Antibiotic agents should be chosen according to the predominant pathogens at a given site of infection in the hospital environment.
- Reduction in hospital stay. It is well known that long inpatient stays prior to surgery lead to a greater incidence of nosocomial infections.
- Early removal of indwelling urethral catheters, as soon as allowed by the patient's condition.
- Nosocomial UTIs are promoted by bladder catheterization as well as by ureteral stenting.
- Antibiotic prophylaxis does not prevent stent colonization, which appears in 100% of patients with a permanent ureteral stent and in 70% of those temporarily stented.

- Use of closed catheter drainage and minimization of breaks in the integrity of the system.
- Use of the least invasive method to release urinary tract obstruction until the patient is stabilized.
- Attention to simple everyday techniques to assure asepsis, including the routine use of protective, disposable gloves, frequent hand disinfection, and infectious disease control measures to prevent cross infections.

Preoperative evaluation

All patients who are being considered for genitourinary surgery should be evaluated with a complete medical history, physical examination, and laboratory tests, including an obligatory urine culture; this will identify those patients with a high risk for development of an infectious complication [18].

Risk factors for infectious complication

There are well recognized risk factors that for academic purposes can be categorized under the following headings (Table 4.1).

Related to the patient

There are several patient characteristics known to increase the risk of infectious complication after surgery. Patients who are immunosuppressed secondary to diverse causes, among others those with malignant or autoimmune diseases receiving chemotherapy or chronic use of corticosteroids usually have impaired infection resistance. Also patients of advanced age or poor nutritional status, with diabetes, obesity, significant kidney or liver diseases, and female patients have a higher risk [6]. Other related factors are the presence of a coexistent infection at another site at the time of surgery or prolonged hospitalization.

Related to urinary tract diseases

Urologic patients are at risk of developing infectious complications because of specific factors related to urinary diseases or their management, both increasing the possibility of colonization and chronic bacteriuria. Risk factors in urologic patients are: anatomic anomalies, voiding dysfunction, urinary diversion, active UTI, obstruction of the urinary tract, stone disease, indwelling catheters, and endogenous material, such as ureteral stents.

Many of these patients will have a positive urine culture and must receive preoperative antibiotics appropriately tailored to culture-specific organisms; at the end of treatment urinary evaluation must be repeated. Rao *et al*. reported that bacteriuria and pyuria are risk factors for bacteremia; they also found that preoperative bacteriuria had a positive predictive value (PPV) of 0.53 for detection of endotoxemia, another important risk factor for the development of urosepsis [19].

Related to procedure

Any procedure performed in patients with urolithiasis is high risk for postoperative infection due to bacterial colonization of the urinary tract, infection stones, or urinary drainage obstruction and indwelling catheters. A lengthy operation or high intrapelvic pressures during endourologic procedures, such as percutaneous or retrograde renal surgeries, carries a high risk of postoperative infection. Finally, open or laparoscopic surgeries, which involve the gastrointestinal or genital tract, such as urinary diversions or vesicovaginal fistula repair, also should be considered high-risk procedures for infection.

These factors frequently act in an additive manner, compounding their impact. The likelihood of bacterial invasion is also affected by the amount of bacteria at the

Table 4.1 Risk factors associated with postoperative infectious complications in genitourinary surgery.

Related to patient	Related to urinary tract diseases	Related to procedure
Immunosuppression:	Chronic bacteriuria	Stone disease management
Malignancy	Voiding dysfunction	Incisional therapy
Autoimmune diseases	Urinary diversion	Surgery of long duration
Chronic corticosteroid use	Obstruction	Involvement of genital tract
Diabetes mellitus	Stone disease	Involvement of gastrointestinal tract
Poor nutritional status	Indwelling catheters	Prosthesis
Severe kidney or liver dysfunction	Endogenous material (ureteral stents)	
Advanced age	Anatomic anomalies	
Female	Impaired urinary flow	
Distant coexistent infection		
Prolonged hospitalization		

site of the surgical procedure. All procedures invading the urinary tract are considered "clean–contaminated." The likelihood of bacterial invasion is increased if bacteriuria is present or good wound preparation and surgical techniques are not employed [9].

Antibiotic prophylaxis

Prophylaxis means a brief course of antibiotics administered before or at the start of an intervention, and is used to minimize the infectious complications resulting from diagnostic and therapeutic interventions. While the rationale for the use of antibiotics is well accepted, possible side effects and development of antimicrobial resistance patterns are potential risks. Therefore, an antibiotic prophylaxis policy should be well considered and based on high levels of evidence [3].

Surgical antimicrobial prophylaxis is recommended only when the potential benefit exceeds the risks and anticipated costs; it has been demonstrated in a variety of settings that surgical antimicrobial prophylaxis, by reducing the incidence of surgical site infections, reduces costs. Conversely, excess and/or inappropriate antimicrobial prophylaxis increases costs, which is reversed by measures to improve compliance with evidence based recommendations [20].

In considering prophylactic treatment, the surgical site and the properties of the antimicrobial agent should be taken into account. The agent should achieve serum and tissue levels that exceed the minimum inhibitory concentration for organisms characteristic of the operative site. Furthermore, the optimal agent should have a long half-life so as to maintain sufficient serum and tissue concentrations for the duration of the procedure without the need for redosing. It should be safe, inexpensive, and unlikely to promote bacterial resistance [4].

For prophylactic antimicrobial administration to be optimally effective, timing and dosing are critical. Infusion of the first dose should begin within 60 min of the surgical incision (with the exception of 120 min for intravenous fluoroquinolones and vancomycin). Correct dosing is equally important. Some drugs should be adjusted to the patient's body weight. Oral administration is as effective as the intravenous route for antibiotics with sufficient bioavailability. This is recommended for most interventions, when the patient can easily take the drug between 1 and 2 h before intervention. Additional doses are required intraoperatively if the procedure extends beyond two half-lives of the initial dose [21]. With few exceptions, the published literature suggests that antimicrobial prophylaxis is unnecessary after wound closure or upon termination of an endoscopic procedure; in most cases, antimicrobials should be given in a single dose, or at least discontinued within 24 h of the end of the procedure.

Three circumstances in which a longer duration of antimicrobials is frequently considered include the placement of prosthetic material, the presence of an existing infection, and the manipulation of an indwelling tube [22]. In cases where an existing infection is present, a therapeutic course of antimicrobials should be administered in an attempt to sterilize the field. In the absence of pre-existing bacterial colonization, there is no evidence that prophylaxis should extend beyond 24 h following a procedure. In cases where prolonged catheterization follows the procedure (e.g. radical prostatectomy), antimicrobial therapy at the time of catheter removal may be therapeutic rather than prophylactic, since colonization has likely occurred. An alternative is to culture the urine 24–48 h prior to the intended catheter removal, and administer culture-directed therapy. This is not practical in cases of catheterization for only 48–72 h. An option then is to administer antimicrobial treatment empirically [4].

The use of preoperative antibiotics can reduce the risk of surgically related infection. Table 4.2 summarizes the recommendations for best practice in antibiotic prophylaxis in urologic surgery from the recently published EAU and AUA guidelines [4, 5].

Preoperative antibiotics and preventive measures of sepsis in specific procedures

Endourologic surgery and shock-wave lithotripsy

Although infection or sepsis may occur despite a sterile preprocedure urine culture, every effort should be made to sterilize the urinary tract before instrumentation. Preoperative treatment with culture-specific antibiotics and subsequent documentation of successful treatment is imperative.

While having a preoperative negative urine culture is desirable for all endourologic procedures, this is not always possible, mainly because of stone or urinary tract colonization. In these cases, appropriate antibiotic therapy should start at least 1 week before the planned procedure.

Shock-wave lithotripsy

The use of prophylactic antimicrobial treatment in patients who undergo shock-wave lithotripsy (SWL) is debated in the literature. The AUA recommends that all patients who are submitted to treatment with SWL receive prophylaxis, quoting a meta-analysis that showed prophylaxis reduced postprocedural bacteriuria from 5.7% to 2.1% [4]. In contrast, the EAU does not recommend the routine use of antibiotic prophylaxis, but suggests the use of prophylaxis in cases at risk of

Table 4.2 Recommended antimicrobial prophylaxis in genitourinary surgery and procedures (modified from [4, 5]).

	Indication		Antimicrobial scheme			
Procedure	AUA	EAU	First choice	Alternative	Duration	Remarks
Diagnostic procedures						
Cystography Cystoscopy Ureteroscopy Uodinamycs	If risk factors	If risk factors	Fluoroquinolone or Second-generation cephalosporin or TMP–SMX	Aminoglycoside ± ampicillin Amoxacillin/clavulanate	≤24 h	If urine culture is negative, antimicrobial prophylaxis is not necessary
Prostate biopsy	All	All	Fluoroquinolone or TMP–SMX	Aminoglycoside + metronidazole or clindamycin	≤72 h	
Endourologic surgery and shock-wave lithotripsy						
Shock-wave lithotripsy	All	In patients* at risk	Fluoroquinolone or TMP–SMX or second-/third-generation cephalosporin	Aminoglycoside ± Ampicillin Amoxacillin/clavulanate	≤24 h	*Patients with ureteral stent, nephrostomy Obstruction and infection stone
TURP/TURBT	All	Only in patients at risk**	Fluoroquinolone or TMP–SMX or second-/third-generation. cephalosporin or aminopenicillin/BLI	Aminoglycoside Ampicillin First-generation cephalosporin Amoxacillin/clavulanate	≤24 h	**Consider in large necrotic tumors
Ureteroscopy	All	Only in patients at risk	Second-/third-generation cephalosporin or TMP–SMX or aminopenicillin/BLI Fluoroquinolone	Aminoglycoside ± ampicillin First-generation cephalosporin Amoxacillin/clavulanate	≤24 h	
Percutaneous renal surgery	All	All	Second-/third-generation cephalosporin or TMP–SMX or aminopenicillin/BLI	Ampicillin/sulbactam Fluoroquinolone First-generation cephalosporin	≤24 h	Length of short course to be determined, intravenous route suggested

Open or laparoscopic surgery						
Clean operations	If risk factor	All	First–generation cephalosporin	Clindamycin	Single dose	Consider in high risk and short postoperative catheter treatment
Clean–contaminated (opening of urinary tract)	All	All	Second-/third-generation cephalosporin or aminoglycoside + metronidazole or aminopenicillin/BLI	Ampicillin/sulbactam Fluoroquinolone	Single perioperative course	
Contaminated (involving intestine)	All	All	Second-/third-generation cephalosporin Aminoglycoside + metronidazole or clindamycin	Ampicillin/sulbactam Ticarcillin/clavulanate Pipercillin/tazobactam Fluoroquinolone	≤24 h	For surgery involving the colon, bowel preparation with oral neomycin plus either erythromycin base or metronidazole can be added
Implanted prosthetic devices	All	All	Aminoglycoside _ First-/second-generation cephalosporin orvancomycin	Ampicillin/sulbactam Ticarcillin/clavulanate Pipercillin/tazobactam	≤24 h	

TURP, transurethral resection of prostate; TURBT, transurethral resection of bladder tumor; TMP–SMX, trimethoprim–sulfamethoxazole; AUA, American Urological Association; EAU, European Association of Urology; BLI, beta-lactamase inhibitor.

Table 4.3 Key points in prevention of infection/sepsis in shock-wave lithotripsy.

1. Identify risk factors **2.** Rule out active UTI preprocedure **3.** Obtain preoperative negative urine culture (ideally)* **4.** Antimicrobial prophylaxis (AMP) if one of the following:** • Obstruction • Presence of an indwelling stent or catheter • Infection stones • Periprocedure stone or urologic manipulation (stone mobilization, double-J stent insertion)

*In bacterial persistence or chronic bacteriuria administer at least three days of culture specific antibiotics before shock-wave lithotripsy.
**American Urological Association guidelines recommends AMP in all cases.

Table 4.4 Key points in prevention of infection/sepsis in transurethral resection of prostate (TURP)/transurethral resection of bladder tumor (TURBT).*

1. Identify high-risk patients **2.** Discard active UTI preprocedure **3.** Obtain a preoperative negative urine culture (ideally)** **4.** Antimicrobial prophylaxis (AMP) in all cases:*** • Maintain closed urinary drainage system • Avoid prolonged catheterization (>3 days)

*Applicable to other transurethral procedures with manipulation.
**In chronic bacteriuria or catheterized patients administer 3–7 days of culture-sensitive antibiotics before surgery.
***For TURBT, EAU guidelines recommend AMP only in the presence of risk factors or large and/or necrotic tumors.

infection, such as those with an indwelling stent or catheter, or infection stones [5].

Skolarikos *et al.*, from the results of a meta-analysis, also suggest prophylaxis is useful only in patients with the above-mentioned risk factors, as well as in patients who undergo preprocedure stone or urologic manipulation at the time of SWL [23]. More recently, Duvdevani *et al*. have supported these recommendations based on similar findings [24].

Although the rate of bacteremia post SWL is reported to be as high as 14%, the rate of sepsis is less than 1%, and the use of prophylaxis remains controversial [25]. The key points in prevention are listed in Table 4.3.

Transurethral surgery (Table 4.4)

Transurethral resection of prostate

UTIs and other infectious complications can be present in 1–26% of patients treated with transurethral resection of prostate (TURP). Risk factors associated with postoperative bacteriuria are operative time, disconnection of the closed urine drainage system, prolonged postoperative catheterization (≥3 days), and preoperative catheterization (within 1 month prior to surgery) [26, 27]. TURP is the most studied procedure regarding the use of antibiotic prophylaxis. Two large meta-analyses have been published, including 38 and 32 randomized clinical trials (RCTs), respectively, and both concluded that the benefit obtained from antibiotic prophylaxis in TURP is sufficiently well demonstrated [28, 29]. The incidence of bacteriuria is reduced (26% to 9%), as is that for clinical sepsis (4.4% to 0.7%). Wagenlehner *et al*., in a large, prospective multicenter study, compared two antibiotics regimens versus a control group; they found that the patients receiving antibiotics showed lower levels of bacteriuria compared with controls and demonstrated that the presence of bacteriuria post TURP (CFU $>10^4$/mL) is a risk factor for infectious complications [30]. There was no statistical difference between antibiotic regimens. Bacteriuria is not considered to be an infectious complication but the last study showed that there is a correlation between bacteriuria and the development of infectious complications.

The AUA guidelines recommend the use of antimicrobial prophylaxis in all patients. The suggested antimicrobial prophylaxis is fluoroquinolone or trimethoprim–sulfamethoxazole as antimicrobial of first choice, and alternatively a first- or second-generation cephalosporin, aminoglycosides ± ampicillin or amoxicillin/clavulanate, before the start of TURP and until less than 24 h postoperatively [4]. The EAU guidelines recommend a very similar antibiotic regimen in all patients other than those at low risk or with a small prostate [5].

Transurethral resection of bladder tumor

The AUA guidelines recommend the same regimen of antimicrobial prophylaxis mentioned above for TURP in all patients undergoing transurethral resection of bladder tumor (TURBT). In contrast, the EAU guidelines recommend that antimicrobial prophylaxis for TURBT is unnecessary unless the patient has some risk factors for infectious complications, or a large tumor requiring a prolonged resection time, or a necrotic tumor. Scientific evidence supports the recommendation by the EAU in two well conducted studies that did not showed any difference between antibiotics and placebo in term of reduce the rate of bacteriuria [31, 32]. More recently, Yokohama *et al*. in a prospective,

randomized study in patients with no risk factors for complications corroborated these findings; no differences were found in terms of infectious complications between groups given antibiotics or placebo. The authors concluded that antibiotics might be deferred and only given to patients who develop postoperative infections [33].

Other transurethral procedures

Other transurethral procedures involving manipulation, like bladder biopsy, laser prostatectomy, and internal uretrotomy, may be similar in terms of tissue trauma, and the AUA guidelines suggest that data regarding TURP and TURBT could be extrapolated to these procedures.

Ureteroscopy

As with other endourologicl procedures, the routine use of antimicrobial prophylaxis for ureteroscopy in patients with a sterile preoperative urine culture is controversial. Assessment of urine for sterility by midstream urine specimen (MSU) culture and sensitivity (C&S) is recommended by most endourologists as an essential prerequisite for endoscopic stone treatment. Nevertheless, MSU cultures do not always correlate with obstructed urine or stones, and sepsis may present in 1% of cases who have a negative MSU culture. Mariappan *et al*. in a prospective study cultured MSU, renal pelvic urine, and obstructing ureteric stones from patients who had undergone ureteroscopic lithotripsy [34]. Clinical bacteremia was seen in 19%. Of these, 58.3% developed features of systemic inflammatory response syndrome (SIRS). Blood and stone C&S were positive in 25% of cases and pelvic urine C&S was positive in 66.7%, but none had a positive MSU C&S (P = .04). Because of the potential for infection or the presence of infection stones, antibiotic prophylaxis is indicated when ureteroscopy is performed for treatment of urinary tract calculi. Few randomized and prospective trials have explored the role of antibiotic prophylaxis in ureterolithotripsy. Knopft *et al*. compared a single preoperative dose of levofloxacine versus placebo, and found the rate of postoperative significant bacteriuria to be significantly higher in the placebo group than in the group given prophylaxis [35].

Indications for antibiotics are less clear for diagnostic ureteroscopy or treatment of tumors. The risk of infection and sepsis, albeit low (3.4% and 0.3–2%, respectively), outweighs the potential benefits, such as cost savings, that may be associated with no antibiotic administration for therapeutic proposes [36]. Current AUA and EAU recommendations for antimicrobial prophylaxis are given in Table 4.2.

Table 4.5 Key points in prevention of infection/sepsis in therapeutic ureteroscopy.

1. Identify high risk patients
2. Discard active UTI preprocedure
   - *Never* perform stone manipulation or incision therapy in active UTI
   - Relieve urinary obstruction, treat infection, and carry out a staged treatment
3. Ensure a preoperative negative urine culture (ideally)*
4. Antimicrobial prophylaxis in all cases
5. Maintain low intrarenal pressure during procedure.

Options:
   - Periodic drainage through ureteroscope or use of ureteral access sheath or angiographic catheter
   - Continuous or intermittent bladder drainage

*In chronic bacteriuria administer at least 3 days of culture-sensitive antibiotics before instrumentation.

Modifiable intraoperative factors may influence infectious complications (Table 4.5). During ureteroscopy, the hydrostatic pressure generated by the irrigation fluid results in bacterial and endotoxin translocation into the systemic circulation; therefore, a low-pressure irrigation system can reduce the incidence of systemic infection. Only enough irrigation to maintain adequate visibility should be used, and renal pressure should be kept as low as possible with the use of a ureteral access sheath (UAS) or angiographic catheter, or periodic drainage of the collecting system through the ureteroscope. In addition, continuous or intermittent bladder drainage with a small-caliber bladder catheter will help maintain low intrarenal pressures during ureteroscopy [36]. Auge *et al*. found that by using a UAS during ureteroscopic stone surgery, pressures in the urinary tract could be significantly reduced. Flexible ureteroscopy was performed with and without the aid of the UAS while pressures were measured via the nephrostomy tube connected to a pressure transducer. With the ureteroscope positioned in the distal ureter, the mean intrarenal pressure without the UAS was 60 mmHg versus 15 mmHg with the UAS; with the ureteroscope in the renal pelvis the pressures were 94.4 mmHg and 40.6 mmHg, respectively [37].

Percutaneous renal surgery

Percutaneous renal surgery has a low reported incidence of urinary sepsis (0.3–1%), but a high mortality rate (66–80%). It is generally agreed that patients who are scheduled for percutaneous nephrolithotomy (PCNL) must have a negative urine culture before surgery. Unfortunately, this is not always possible to adhere to because of stone or urinary tract colonization; in these patients, appropriate antibiotic therapy

Table 4.6 Key points in prevention of infection/sepsis in percutaneous renal surgery.

1. Identify high-risk patients
2. Discard active UTI preprocedure
• *Never* perform stone manipulation or incision therapy when active UTI!
3. Ensure sterile urine preoperatively (ideally)*
4. Antimicrobial prophylaxis in all cases
5. Stop procedure if purulent fluid is obtained at puncture, leave a nephrostomy tube, and stage treatment**
6. Maintain low intrarenal pressure during procedure:
• Use only enough irrigation to maintain adequate visibility
• Use a wide renal access sheath, ideally 4F wider than nephroscope
7. Limit quantity of irrigation fluid and operative time

*In chronic or asymptomatic bacteriuria administer at least 7 days of culture-sensitive antibiotics before surgery.
**Obtain pelvic urine culture and treat infection completely.

should start at least 1 week before the planned procedure (Table 4.6).

Results of urine cultures from patients with stones are not predictive of stone bacteriology, especially in those with struvite stones. Therefore, this group should receive broad-spectrum antibiotic therapy that is specific to the cultured bacteria but also likely to be effective against urease-producing organisms residing in the stone.

Mariappan *et al*. demonstrated that stone and pelvic urine cultures obtained during surgery are better predictors of potential urosepsis than bladder MSU [38]; they found that bladder urine cultures were positive in 11.1% of cases versus 35.2% and 20.4% of stone and pelvic urine cultures, respectively. Stone culture showed the greatest PPV (0.7). Infected bladder urine did not always carry identical bacteria to those found in the upper tract. Patients with pelvic- or stone-positive cultures showed a relative risk for urosepsis at least four times greater than the rest of the cohort. In this study, bladder urine did not predict SIRS. Also, they found that preoperative hydronephrosis and stones larger than 20mm correlated with positive stone and pelvic urine cultures.

The published literature suggests that antimicrobial prophylaxis is unnecessary after wound closure or on termination of an endoscopic procedure, but because PCNL can be associated with a pre-existing infection, infectious stone, or manipulation of an indwelling catheter, the subsequent course of antimicrobials that is therapeutic rather than prophylactic might extend beyond 24h from the conclusion of the procedure. In the absence of pre-existing bacterial colonization, there is no evidence that prophylaxis should extend beyond 24h. In cases where prolonged catheterization follows the procedure (i.e. nephrostomy tube), antimicrobial therapy at the time of catheter removal may be therapeutic rather than prophylactic, because colonization likely has occurred. A recommended antimicrobial regimen is given in Table 4.2.

Renal pelvic pressure (RPP) greater than 30mmHg has been shown to result in pyelovenous–lymphatic backflow. Troxel and Low, in a prospective study that included 31 patients, found that during PCNL pressures greater than 30mmHg were recorded in only eight (26%) patients and no association was seen between RPP and postoperative fever [39]. Contrary to this, Zhong *et al*. demonstrated that mean intrapelvic pressure greater than 20mmHg and accumulated time of RPP greater than 30mmHg may cause enough backflow to contribute to bacteremia and postoperative fever [40]. Low RPP during surgery is achieved using an open low-pressure access system, such as operating through an Amplatz sheath (operating instrument 4F sizes smaller than the access sheath). Inflow of irrigant should be at gravity and never pressurized. We also recommend the use of forced diuresis (furosemide 20mg at the beginning of irrigation and every 60 min of surgery and irrigation time) to reduce further the pyelorenal reflux that potentially causes fluid overload and bacteremia. Others factors that have been related to postoperative fever and risk of bacteremia are long operative time, large stone burden, and large amounts of irrigating fluid.

Manipulation of infected stones can cause sepsis due to endotoxemia. McAleer *et al*. measured endotoxins levels in renal stones and found markedly higher levels in infection stones [41]. Interaction of bacteria with different intracorporeal lithotripters may have antibacterial effects. *In vitro* studies have shown a decrease of bacteria viability after use of intracorporeal lithotripsy and laser [42]. Our group has reported recently that extracorporeal shock-wave or intracorporeal lithotripsy, using all the alternatives currently available, are significantly effective at reducing the viability of bacteria located inside artificial stone models, including struvite stone models infected with *Proteus mirabilis* [43–45]. Whether this bactericidal effect is desirable is still to be answered, because reduction in the number of bacteria may represent an increase in the presence of proteins/endotoxins liberated from bacterial cell lysis, therefore increasing the risk of urosepsis.

In the presence of an obstruction at the ureteropelvic junction (UPJ) or intrarenal segments (stone, stricture, or tumor), infected urine may be encountered despite previous negative cultures of the voided urine. In such

instances, treatment has to be postponed, the urine cultured, and the renal collecting system drained under antibiotic coverage until eradication of the infection is documented. According to Ramsey *et al*. in a recent evidence-based review [46], the effects on the resolution of infected hydronephrosis are similar if a ureteral stent or a nephrostomy tube is used, nevertheless Mokhmalji *et al*., in a prospective randomized study, reported prolonged fever and catheter placement time in the group of patients treated with ureteral stent, and suggest that percutaneous nephrostomy is superior to ureteral stents for diversion of hydronephrosis [47].

Small case series have been reported that explore the possibility of continuing the surgery even if purulent urine is encountered incidentally. Aron *et al*., in a group of 19 patients, reported no difference regarding the incidence of postoperative fever or sepsis between patients with one-stage versus staged surgery with collecting system drainage and 3–7 days of intravenous antibiotic coverage before a second procedure [48]. Hosseini *et al*. divided 45 patients into two groups: in group 1 (n = 29), stones were removed during the first session; and in group 2 (n = 16), a nephrostomy tube remained in place, and stone removal was accomplished 3–5 days later when results of urine and nephrostomy fluid cultures were negative [49]. They reported no intraoperative or postoperative complications, other than transient fever in 10.3% and 12.5% in groups 1 and 2, respectively. In spite of these recent reports, there is neither sufficient evidence nor well designed clinical trials to recommend other conduct than performing a staged procedure with drainage and broad-spectrum antibiotic therapy until infection has resolved.

Open and laparoscopic urologic surgery

Surgical wound classification into the categories clean, clean–contaminated, contaminated, and dirty seems as relevant to urologic surgery as it is for general surgery [50].

Clean surgery

This category involves surgery performed in uninfected tissues without opening of the urinary tract and with primary closure of the wound. Montgomery *et al*., in a prospective but nonrandomized trial, compared 424 hand-assisted laparoscopic nephrectomies with and without antimicrobial prophylaxis (cephalosporin preoperatively), and found that omission of antibiotic prophylaxis was significantly associated with an increased rate of incision site infections (13% vs 5.4%) [51]. Steiner *et al*. randomized a group of 83 patients undergoing open transabdominal radical nephrectomy to a single dose of intravenous third-generation cephalosporin (n = 39) versus no antimicrobial prophylaxis (n = 44) and found a significantly lower overall infection rate in the prophylaxis group (7.7% vs 27.3%) [52].

Clean–contaminated surgery

The urinary tract is entered under controlled conditions and there are no infected tissues or bacteriuria. Surgery involving bowel tissue is also classified as clean–contaminated. According to the EAU guidelines for UTI, prophylactic antibiotics are not recommended for open procedures that do not involve bowel segments, except in patients who are at increased risk of infection, as occurs with long-term urinary drainage. The expected rate of febrile UTI in surgeries that enter the urinary tract is close to 10% without prophylaxis; antimicrobial prophylaxis can be expected to significantly reduce this rate to 2–3% [53]. Regarding the optimal duration of perioperative prophylaxis, one randomized and controlled trial confirmed that 1 day of intravenous second-generation cephalosporin was as effective as 4 days of the same agent in the prevention of postoperative infections after radical prostatectomy [54]. Stranne *et al*. also found in a prospective study that a single dose of antibiotic (a quinolone) given before radical retropubic prostatectomy appears to be sufficient prophylaxis [55].

Contaminated and dirty surgery

The presence of a nontreated infection, including UTI, should be considered as contaminated urologic surgery. When pus is present, the surgery is labeled dirty.

In *contaminated* and *dirty* operations, antimicrobial agents are given with a therapeutic intention. Infected urine is a very high risk factor for both surgical site infections in, for example, open prostatectomy, and febrile UTI after TURP. Casey *et al.* reported an incidence of infectious complication of 20% in patients with chronic bacteriuria undergoing major urologic surgery, and they found that wound infections were as common in patients whose urine cultures revealed multiple unsuspected organisms as in those who were resistant to the perioperative antibiotics [56]. Patients with an indwelling catheter, nephrostomy tube, or other stent device should be considered as having bacteriuria and must be treated in advance (between 3 and 7 days prior to the operation) in order to favor sterile urine at the time of surgery. The patient should be covered well beyond the intervention (7–10 days or longer), depending on the type of operation and patient factors [57].

Since infectious complications are potentially serious when they involve prosthetic material, antibiotic coverage is advocated irrespective of surgical category [50].

Use of antibiotics in patients with indwelling catheters, stents, and drainage tubes

The most important risk factor in the development of catheter-associated bacteriuria is the duration of catheterization. Most episodes of short-term catheter-associated bacteriuria are asymptomatic and are caused by a single organism. Multiple organisms tend to be acquired in patients catheterized for more than 30 days.

The clinician should be aware of two priorities: the catheter system should remain closed and the length of catheterization should be minimal. While the catheter is in place, systemic antimicrobial treatment of asymptomatic catheter-associated bacteriuria is not recommended, except for some special cases. Routine urine culture in an asymptomatic catheterized patient is also not recommended because treatment is in general not necessary. Antibiotic treatment is recommended only for symptomatic infections.

Long-term antibiotic suppressive therapy is not effective. Antibiotic irrigation of the catheter and bladder is of no advantage. Routine urine cultures are not recommended if the catheter is draining properly. A minority of patients can be managed with the nonreturn (flip) valve catheter, which avoids the need for a closed drainage bag. Such patients may exchange the convenience of on-demand drainage for an increased risk of infection.

Alternatives to indwelling urethral catheters that are less prone to cause symptomatic infection should always be considered. In selected patients, suprapubic catheters, condom drainage systems, and intermittent catheterization are preferable to indwelling urethral catheters [5]. Intermittent catheterization is recommended whenever the patient is able to self-practice this alternative. Prophylactic antimicrobials have not been demonstrated to be beneficial in patients undergoing clean intermittent catheterization [57]. The rate of bacteriuria even in short-term catheterized patients is 5–10% for each day that the catheter is in place [58].

When continuous urinary drainage is required after surgery, perioperative antibacterial prophylaxis is not recommended unless a complicated infection requiring treatment is suspected. Asymptomatic bacteriuria (bacterial colonization) is only to be treated prior to surgery or after removal of the drainage tube. Treatment of a patient at the time of removal of an external urinary catheter should be based on culture-directed antimicrobials. An analysis in the Cochrane Database of Systematic Reviews concluded that there is limited evidence that antimicrobials during the first 3 postoperative days, or from postoperative day 2 until catheter removal, reduces the rate of bacteriuria and other signs of infection in surgical patients [59].

In patients with indwelling double-J stents, two RCTs showed that the rate of bacterial colonization depends directly on underlying pathologies, time of stenting, and female sex [60, 61]. Low-dose antibiotics for patients with temporary double-J stents are not recommended and have been shown to increase the risk of acquiring bacterial resistance [62, 63]. Recent advances in stent design have lead to the development of some drug-eluting catheters with the aim of reducing the biofilm and thus the stent colonization. In a rabbit model, triclosan reduced bacterial growth and *P. mirabilis* survival, preventing stent-related UTIs [64].

Postoperative sepsis: early identification and initial treatment

Early recognition and management of sepsis optimizes outcome. Therefore, patients in whom this problem is suspected after genitourinary surgery should be prioritized and receive timely care.

To diagnose sepsis and severe sepsis/septic shock as early as possible, it is necessary to have clear definitions of infection, organ dysfunction, and global tissue hypoxia, and to recognize the clinical and laboratory findings that are indicative of these conditions.

Sepsis is defined as the presence of SIRS caused by a documented or suspected infection. SIRS is defined as the presence of two or more of the following: (1) temperature greater than 38°C or less than 36°C; (2) heart rate greater than 90 beats/min; (3) respiratory rate greater than 20 breaths/min (or $PaCO_2 < 32$ torr); and (4) white blood cell count greater than $12\,000/mm^3$ or greater than 10% immature band forms.

Severe sepsis is defined as the presence of sepsis and one or more organ dysfunctions. Organ dysfunction can be defined as acute lung injury; coagulation abnormalities; thrombocytopenia; altered mental status; renal, liver, or cardiac failure, or hypoperfusion with lactic acidosis.

Septic shock is defined as the presence of sepsis and refractory hypotension, i.e. systolic blood pressure less than 90 mmHg and unresponsive to a crystalloid fluid challenge of 500 mL.

As mentioned above, clinical and laboratory recognition of septic problems is mandatory. Procalcitonin is a propeptide of calcitonin, but lacks hormonal activity. During generalized infections with systemic manifestations, its level may rise considerably. In contrast, during severe viral infections or inflammatory reactions of non-infectious origin, procalcitonin levels show no or only a moderate increase. Its exact site of production during inflammatory response is still unknown. The documentation of high levels of early biochemical markers, such as procalcitonin and protein C, in the initial postoperative period may help identify a severe inflammatory

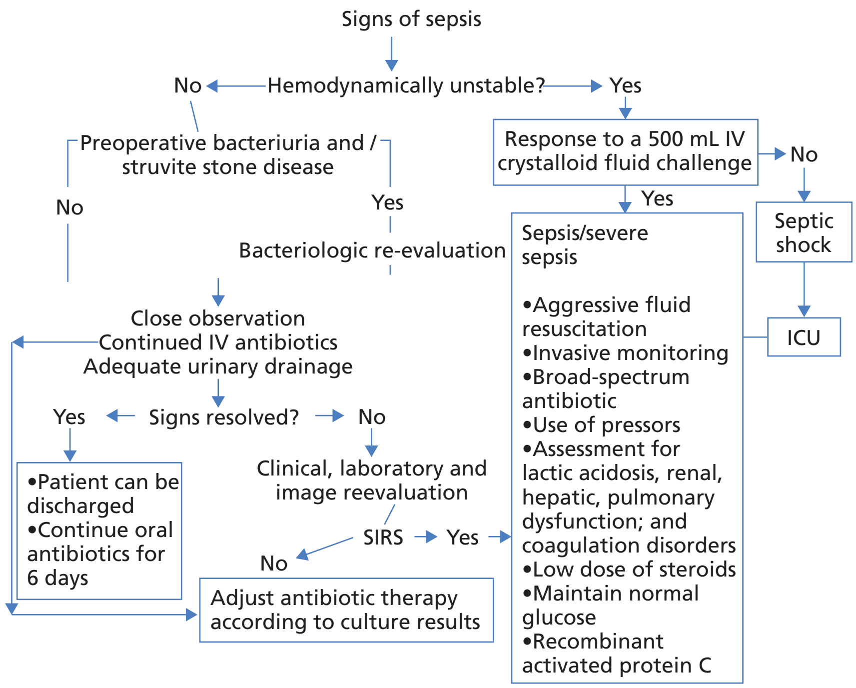

Figure 4.1 Postoperative management of a patient suspected of or diagnosed with sepsis. ICU, intensive care unit; SIRS, systemic inflammatory response syndrome.

response to surgical stress from bacteremia, SIRS, or sepsis/septic shock, and prompt the institution of adequate and opportune therapeutic measures [65].

Appropriate therapy is a continuum of infection management ranging from drainage (maintaining indwelling catheter or opening the nephrostomy tube in cases of percutaneous renal surgery and broad spectrum antibiotics, to aggressive fluid resuscitation and invasive monitoring with medical management in the intensive care setting until the causative agent is found and eradicated (Figure 4.1).

Continuous monitoring of vital signs, pulse oximetry, urine output, and initial laboratory testing to assess the severity of global tissue hypoxia and organ dysfunction, including assessment for lactic acidosis, renal and hepatic dysfunction, acute lung injury, and coagulation abnormalities, should be instituted as soon as possible in patients in whom severe sepsis/septic shock is suspected to facilitate the earliest recognition of this condition.

The usual bacteria cultured from urinary sources are aerobic Gram negative bacilli and enterococci. Appropriate cultures (including blood and urine) should be obtained before the adjustment of antibiotics. At this point, it is important to reanalyze urine cultures that were obtained preoperatively or during surgery and, based on their results, redirect antibiotic therapy. If results are not available, empiric broad spectrum antibiotics should be initiated as soon as possible. Suggested primary regimens include the usage of ampicillin/gentamicin, or piperacillin–tazobactam, or carbapenems (doripenem, imipenem, or meropenem); the duration of treatment is determined by the patient's clinical response. It is imperative to modify the antibiotic regimen to a culture directed one when possible.

If severe sepsis/septic shock is recognized, besides empiric antibiotic therapy, prompt treatment in the intensive care unit should include repletion of intravascular volume with large amounts of crystalloid intravenous fluids. Pressors are administered as needed to maintain blood pressure, central venous pressures are monitored, and fluids are administered to maintain a pressure of 8–12 cmH_2O. Bicarbonate and low-dose steroids may be used and good blood glucose control maintained. Tight blood glucose control by administration of insulin doses up to 50 U/h is associated with a reduction in mortality. Recombinant activated protein C (dotrecogin alpha) is a new drug that has been approved for therapy of severe sepsis. Multidisciplinary treatment is essential to obtain good results [7, 10, 66, 67].

Conclusions

Septic complications in genitourinary surgery are a life-threatening scenario that urologists wish to avoid during their practice. To achieve this goal or to minimize the

risk of sepsis, a thorough medical history must be performed in order to identify patient risk factors; it is necessary to assess the appropriate time to perform surgery according to the potential infectious sources and to provide correct preoperative prophylaxis and follow-up. Once an infectious complication is suspected, it is imperative to act fast and accurately in a multidisciplinary fashion to avoid the progression of the natural history of sepsis and to provide a better opportunity for recovery.

CHAPTER 5

Management of Anticoagulation Therapy in Endoscopic and Laparoscopic Urologic Surgery

Michael Poch & George E. Haleblian
Division of Urology, The Warren Alpert Medical School of Brown University, Providence, RI, USA

Introduction

The benefit of anticoagulants has been shown for a number of cardiovascular disorders, including atrial fibrillation, cardiac stent management, and thromboembolic disorders. While these anticoagulants are necessary, they can pose a difficult and complex problem for both the urologist and patient when elective or nonelective procedures need to be performed. Anticoagulants vary in their mechanism of action, half-life, and bleeding risk. This chapter addresses anticoagulants and the management of patients on anticoagulants for specific urologic disorders and procedures.

In order to adequately understand the mechanism of action of the anticoagulants, a brief review of the hemostasis and coagulation cascade is necessary. Hemostasis requires appropriate function of four key components: platelet activation and aggregation, the clotting cascade, termination of clot formation, and fibrinolysis.

Normal hemostasis

Normal hemostasis requires a physiologic balance between prothrombotic and anticoagulant factors. Vascular injury results in the initiation of clotting and is dependent on three components: the vascular wall, platelets, and the coagulation cascade [1].

The initial step of this process is the formation of a platelet plug. This is completed in three steps: adhesion, aggregation, and the secretion of procoagulant proteins that interact between platelets and endothelial cells, as well as between individual platelets. Von Willibrand's factor, glycoprotein (GP) IIb/IIIa, and GP 1b are all proteins that are involved in the formation and propagation of the platelet plug.

The second important step in thrombosis is the initiation of the coagulation cascade. While a thorough discussion of the coagulation cascade is beyond the scope of this chapter, a brief summary is given (Figure 5.1). The coagulation cascade is a series of steps in which proenzymes are converted to activated enzymes, and the final product is fibrin. The cascade is divided between the extrinsic and intrinsic pathways. At the site of vascular injury, the extrinsic pathway is initiated, beginning with the release of tissue factor from endothelial cells. Tissue factor then complexes with Factor VIIa, which activates Factor Xa, and Factor Va which activates prothrombin to thrombin. Factors Xa and Va represent a final common pathway for both the extrinsic and intrinsic pathways. Thrombin has a positive feedback to the intrinsic pathway, activating Factor XII, and through a series of steps, including activation of Factors XI, IX, and VIII, activate Factor Xa and Va and sustain coagulation.

Many of the proenzymes in the coagulation cascade are dependent upon vitamin K as a cofactor, and therefore antagonists such as warfarin will disrupt the coagulation process. Proteins C and S are vitamin K-dependent enzymes that inactivate Factor Va and VIIIa. Antithrombin (AT) neutralizes many of the enzymes of the clotting cascade, in particular thrombin, Factors IXa, Xa, XIa, and XIIa by forming irreversible complexes.

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Drug-mediated anticoagulation

Warfarin

Warfarin is a vitamin K-dependent anticoagulant. It achieves its anticoagulation effect by decreasing levels of vitamin K-dependent clotting factors (Factors II, VII, IX, and X) by indirectly inhibiting carboxylation (and thus activation) of newly synthesized clotting factors through the VKORC1 pathway. This pathway causes oxidative reduction of vitamin K, which then allows for carboxylation of clotting factors from their inactive to active form. Therefore, warfarin administration results in the inability to synthesize active vitamin K-dependent clotting factors. The result of this is a delayed effect of antithrombotic activity until pre-existing active clotting factors are expended. Of the vitamin K-dependent clotting factors, prothrombin (Factor II) has the longest half-life (~60 h), which explains the delay in antithrombotic activity after initiation of warfarin therapy.

Careful monitoring of warfarin levels is mandatory as many variables can influence the efficacy of a given dose. These variables include vitamin K stores/intake, medical conditions (liver disease, thyroid disease, infection, fever, heart failure), and medications (quinolones, antifungals, trimethoprim–sulfamethoxazole, amiodarone, rifampin, barbiturates, levothyroxine, metronidazole). Monitoring is performed by a standardized international normalized ratio (INR). Specific target INR ranges have been developed for many underlying medical diseases requiring warfarin therapy.

Heparin

Unfractionated heparin (UFH) is the most common antithrombin (AT) anticoagulant; and is dependent upon

binding AT and thrombin together in order to mediate thombolysis. It is the mainstay of bridging therapy as its half-life is short and it is given as a continuous infusion. It can be turned off between 4 and 6h prior to elective surgery and resumed after surgery at the surgeon's discretion, based on bleeding risk. UFH is favorable in that the dose can be easily titrated.

Low molecular weight heparin (LMWH) has a similar mechanism of action, but due to its smaller size, it is theoretically less effective at binding AT and thrombin together. It can be given as both intravenous and subcutaneous injection, and therefore anticoagulation management can be performed as an outpatient directed by the clinician.

Bridging therapy with either UFH or LMWH is typically started 36h after the last dose of warfarin. In general, LMWH can be held for 24h prior to elective surgery [2]. Less than 1% of patients will develop heparin-induced thrombocytopenia (HIT) while on UFH, and even fewer with LMHW. Patients who have a history or HIT or develop a history can be bridged with direct inhibitors of thrombin, which include argatoban and lepirudin.

Antiplatelet-mediated anticoagulation

Aspirin (ASA) and thienopyridines inhibit platelet function. Their mechanisms of action, however, differ. Thienopyridines, the most common of which is clopidogrel, inhibit ADP-dependent platelet activation and aggregation by irreversibly disabling the GP IIb/IIIa ligand between platelets. ASA irreversibly inhibits cyclooxygenase-1 (COX-1), which is typically converted to thromoboxane A_2, also required for platelet aggregation. Platelets are unable to generate new COX-1 and therefore ASA inhibition of platelet aggregation lasts the life of the platelet (7–10 days). Nonsteroidal anti-inflammatory drugs (NSAIDs) reversibly inhibit COX-1 and are therefore weaker anticoagulants.

ASA and thienopyridines are used for the treatment and prevention of cardiovascular diseases. There are a number of guidelines regarding indications for use of these medications for prevention; however, in general, patients using this class of medication for prevention of coronary artery disease are at low risk for complications if the medication is stopped during intervention. In contrast, patients with coronary artery stents may be at risk for stent thrombosis when anticoagulant therapy is stopped [3].

Guidelines

Management of anticoagulation in the perioperative period requires an understanding of the underlying pathologic state requiring anticoagulation, e.g. atrial fibrillation, presence of mechanical heart valve, and risk of thromboembolism. For example, those patients with a history of recurrent venous or pulmonary thromboembolism have a risk of recurrence as high as 15%/year. That incidence increases to as high as 50% in the first 3 months after an initial event [4].

In 2008 the American College of Chest Physicians introduced guidelines regarding management of those patients talking vitamin K antagonists [5, 6]. Patients were stratified according to risk (high, moderate, low) of either arterial or venous thromboembolic event based on the underlying need for anticoagulation (Table 5.1). Those patients with a risk greater than 10%/year of a thromboembolic event were considered high risk.

Bridging therapy with heparin is recommended for all high-risk patients, including those with mitral valve prosthesis, recent transient ischemic attack (TIA), and $CHADS_2$ score of 5 or 6. $CHADS_2$ score is a prediction tool for identifying patients with atrial fibrillation who require anticoagulation. Risk factors such as age older than 75 and congestive heart failure (CHF) are each given a point, with a total possible score of 6 (Table 5.2). Those patients with higher risk scores are more likely to have thromboembolic events [7].

Moderate risk (4–10%/year) patients include those with bileaflet aortic prosthesis with an associated cardiac conditions, $CHADS_2$ score of 3 or 4, active cancer, and venous thromboembolism within the past 3–12 months. Bridging therapy is also recommended for those patients with either LMWH or UFH.

For those patients who are low risk (<4%/year), bridging with low-dose LMWH or interruption of vitamin K antagonist is recommended. These patients include individuals with a $CHADS_2$ score of 0–2, a single venous thromboembolic event more than 12 months ago, or bileaflet aortic valve prosthesis without further comorbidities.

Additionally, withdrawal of warfarin can cause a reflex hypercoaguable state. Great caution should be taken when withdrawing and restarting warfarin therapy in patients with certain conditions with known risk of thromboembolism, including antiphospholipid conditions, and protein C and protein S deficiencies [8].

Controversy still exists regarding the minimum length of treatment of patients after percutaneous coronary intervention (PCI) with platelet inhibitors; this depends on the type of stent placed and the risk of bleeding. Rates of stent thrombosis are generally low, however the risk of thrombotic event after placement of drug-eluting stents is highest in those patients in whom clopidogrel has been discontinued [9].

According to recent guidelines from both the American Heart Association, the American College of Cardiology [10], and the American College of Chest Physicians [5], patients with bare metal stents should continue both ASA and clopidogrel for at least 1 month post PCI, and preferably up to 1 year, and patients with drug-eluding stents should continue ASA and clopidogrel for at least

Table 5.1 Patient risk stratification for perioperative arterial or venous thromboembolism [5] (From Douketis JD, Berger PB, Dunn AS, et al. Chest 2008;133(6 Suppl):299S–339S © American College of Chest Physicians).

Risk stratification	Indication for vitamin K anticoagulation therapy		
	Mechanical heart valve	Atrial fibrillation	Venous thromboembolism (VTE)
High	Any mitral valve prosthesis Older (caged-ball or tilting disc) aortic valve prosthesis Recent (within 6 months) stroke or transient ischemic attack (TIA)	$CHADS_2$ score 5 or 6 Recent (within 3 months) stroke or TIA Rheumatic valvular heart disease	Recent (within 3 months) VTE Severe thrombophilia (e.g. deficiency of protein C, protein S or antithrombin, antiphospholipid antibodies, or multiple abnormalities)
Moderate	Bileaflet aortic valve prosthesis and one of the following: atrial fibrillation, prior stroke or TIA, hypertension, diabetes, congestive heart failure, age >75	$CHADS_2$ score 3 or 4	VTE within the past 3–12 months Nonsevere thrombophilic conditions (e.g., heterozygous factor V Leiden mutation, heterozygous factor II mutation) Recurrent VTE Active cancer (treated within 6 months or palliative)
Low	Bileaflet aortic valve prosthesis without atrial fibrillation and no other risk factors for stroke	$CHADS_2$ score 0–2 (and no prior stroke orTIA)	Single VTE >12 months ago and no other risk factors

Table 5.2 $CHADS_2$ score [7].

$CHADS_2$ risk stratification		
	Risk factor	Points
C	Congestive heart failure	1
H	Hypertension 140/90 mmHg	1
A	Age >75	1
D	Diabetes mellitus	1
S	Prior stroke or transient ischemic attack	2

12 months, with almost no exceptions. This makes nonelective noncardiac surgery planning complex as those patients with a new diagnosis of cancer may benefit from placement of bare metal stents rather than drug-eluting stents. Discussion of specific cases should be undertaken with the patient's cardiologist in order to devise a specific plan of care for that particular patient.

Urologic procedures

The management of patients on anticoagulation requires a balance of both the risks and benefits of stopping or continuing the anticoagulation. This is typically based on a number of factors, including the risk of bleeding with a particular intervention both intraoperatively and postoperatively, and the risk of thromoboembolic events when not on anticoagulation.

Cystoscopy

In ideal circumstances, cystoscopy, like the majority of endoscopic procedures, should be an atraumatic intervention. While a paucity of data exists regarding the risk of bleeding during surveillance and diagnostic cystoscopic procedures with either flexible or rigid instruments, it is typically unnecessary to stop any form of anticoagulant during routine diagnostic or surveillance cystoscopy. If that procedure has a risk of being combined with an additional cystoscopic or ureteroscopic intervention, then the risk assessment of anticoagulation should be for the more invasive procedure.

Transurethral resection of the prostate

Over the past 15 years many different technologies have evolved for eliminating obstructive prostatic tissue. The gold standard, transurethral resection of the prostate (TURP), has a significant risk of bleeding requiring transfusion in patients without anticoagulation. In that regard, many clinicians recommend stopping all forms of anticoagulation prior to TURP. For those patients on ASA or NSAIDs, these medications should be stopped 1 week prior to the procedure, while patients on warfarin can either be bridged with heparin or have partial cessation of warfarin therapy. This choice is typically dependent upon the reason for warfarin therapy.

Newer technologies, including laser enucleation or vaporization of the prostate and bipolar resection/vaporization, are thought to be more hemostatic than

traditional TURP. Sandhu *et al*. reviewed 24 patients on anticoagulation with clopidogrel, ASA, or warfarin, who underwent photoselective vaporization of the prostate (PVP) with a high power KTP laser [11]. Those patients taking warfarin discontinued taking it 2 days preoperatively; those taking other anticoagulants continued their treatment. There was no significant change in serum hematocrit, no need for transfusion, and no significant hematuria or clot retention postoperatively.

Studies evaluating bipolar TURP have found decreased intraoperative blood loss and decrease in change of postoperative hematocrit. Fagerstom *et al*. randomized 202 patients to monopolar versus bipolar TURP and found decreased rates of blood loss with the latter [12]. While this study did not evaluate for the presence or absence of anticoagulation, the results may suggest that bipolar TURP may be a safer procedure if anticoagulation cannot be stopped.

Ureteroscopy/renoscopy

Similar to cystoscopy, diagnositc and surveillance ureteroscopy / renoscopy should be able to be performed with minimal trauma to surrounding tissues. In that regard, patients should be able to tolerate continuation of anticoagulation with minimal risk of bleeding. Similar to cystoscopy, there is a paucity of literature to describe the risk of bleeding during these diagnostic procedures. When combined with either biopsy or stone manipulation, the risk of bleeding may increase. Turna *et al*. compared a series of 37 patients on ASA, clopidogrel, or warfarin who underwent ureteroscopy and laser lithotripsy with matched controls [13]. No difference in stone-free rates, intraoperative or postoperative complications, or hemorrhagic or thromboembolic complications were found. None of the patients receiving anticoagulation required early termination of the procedure due to bleeding. Twenty-five patients with bleeding diathesis, including warfarin use, treated for ureteral or renal stone disease were reviewed by Watterson *et al*. [14]. The overall stone-free rate was reported as 96%. There was one episode of retroperitoneal hemorrhage which required transfusion. This was associated with use of an endoscopic hemorrhoidal ligation (EHL) device.

In conclusion, stone manipulation with ureteroscopy and laser manipulation appears to have similar success in those patients on anticoagulation and those who are not. When performing stone manipulation, EHL devices should be avoided because of the increased risk of bleeding.

Percutaneous lithotripsy

Percutaneous urologic procedures are usually performed for management of renal calculus disease. Due to the invasive nature of the procedure and risk of hemorrhage during needle passage, tract dilation, or nephroscopy, uncorrected coagulopathy is an absolute contradindication for percutaneous nephrolithotomy (PCNL) [15]. In non-anticoagulated patients, intraoperative and perioperative hemorrhage is not uncommon. Transfusion rates of up to 34% have been described. Delayed bleeding occurs in approximately 1% of patients [16].

Kefer *et al*. recently published a series of 27 patients on anticoagulation with clopidogrel, warfarin, or cilostazol [17]. Patients on warfarin were bridged with LMWH and warfarin was resumed on postoperative day 5. Patients on cilostazol and clopidogrel stopped these drugs 10 days prior to surgery and resumed them 7 days postoperatively. The overall stone-free rate was 93%. Two patients had significant bleeding while one had a thromboembolic event.

An alternative to PCNL for large stone burden in patients at high risk for cessation of anticoagulation therapy is staged ureteroscopy with laser lithotripsy, as reported by Ricchiuti *et al.* [18]. Twenty-three patients with an average initial stone burden of 3 cm underwent ureteroscopy with laser lithotripsy. No intraoperative complications were reported. Secondary procedures were required in 43% of patients. Stone-free rates were reported as 73.9%.

PCNL appears to be an effective treatment modality for patients who are on anticoagulation that can be safely withdrawn; however, in high-risk patients, a staged ureteroscopic approach has been shown to be an effective option for management of large stones.

Laparoscopy

A description of the full scope of the physiologic effects of laparoscopy is beyond the scope of this chapter. However, uncontrolled coagulopathy is a contraindication to performing laparoscopic surgery. Guidelines for intervention in a laparoscopic setting are similar to those for open surgery, and temporary cessation of anticoagulation or bridge therapy are the hallmarks of management.

Partial nephrectomy

Kefer *et al*. performed a case control study in 47 patients on long-term anticoagulation with warfarin, clopidogrel, or cilostizol, which was appropriately stopped perioperatively [19]. There was no difference in transfusion rate, but a slightly increased intraoperative blood loss and drop in hematocrit in the patients on anticoagulation. There were five thrombotic events in the anticoagulation group and none in the control group.

Varkarakis *et al*. examined 25 patients on chronic warfarin who underwent radical laparoscopic nephrectomy

after bridging with heparin and reported no evidence of increased risk of intraoperative bleeding [20]. However, there was a higher incidence of postoperative bleeding as well as transfusion rate. There were no thromboembolic complications in the anticoagulation group.

With appropriate management of the anticoagulation, both radical and partial laparoscopic nephrectomy can be performed safely on patients who require long-term anticoagulation. Currently, there is no strong evidence to support an increased risk of postoperative bleeding or need for transfusion.

Deep vein thrombosis prophylaxis

In 2008 the American Urological Association (AUA) published guidelines regarding deep vein thrombosis (DVT) prophylaxis for urologic procedures [21]. Defining the risk of DVT is critical in determining appropriate prophylaxis. Factors predisposing patients to DVT include immobility, trauma, malignancy, previous cancer therapy, past history of DVT, increasing age, pregnancy, estrogen therapy, obesity, smoking, venous varicosities, central venous catheterization, myeloproliferative disorders, nephrotic syndrome, and inherited or acquired thrombophilia. Patients should be stratified into low-, intermediate-, high-, and highest-risk categories based upon age and comorbidities (Table 5.3) [21]. In patients undergoing transurethral surgery who are at increased risk for DVT, graduated compression stockings (GCS) and intermittent pneumatic compression (IPC) may be recommended, with a decrease in the incidence of postoperative pulmonary thromboemolism from 0.55% to 0.45% with use of GCS. It is unclear as to the benefit of heparin prophylaxis in this cohort of patients given the conflicting results regarding increased bleeding risk. All patients undergoing laparoscopy or robotic surgery should wear intermittent compression devices as recommended by the AUA guideline panel [21]. Due to the lack of randomized controlled trials for this patient population, there is no consensus regarding the use of pharmacologic DVT prophylaxis. However, patients falling into the high-risk and highest-risk categories should be considered for pharmacologic prophylaxis.

Table 5.3 Patient risk stratification for DVT prophylaxis for urologic procedures (from AUA guidelines for DVT prophylaxis [21]).

Low risk	Minor surgery in patients <40 years with no additional risk factors
Moderate risk	Minor surgery in patients with additional risk factors
	Surgery in patients aged 40–60 years with no additional risk factors
High risk	Surgery in patients >60 years
	Surgery in patients aged 40–60 years with additional risk factors (prior venous thromboembolism, cancer, hypercoagulable state)
Highest risk	Surgery in patients with multiple risk factors (age >40 years, cancer, prior venous thromboembolism)

Conclusions

The management of anticoagulation for endoscopic and laparoscopic urologic procedures is a complex challenge for the clinician. Individual treatment plans for patients need to be developed based on risk stratification for thromboembolic events, the type of anticoagulant, reason for therapy, and the invasiveness and character of surgery. In all instances, risk stratification of the patient is critical in determining the optimal treatment modality. In some circumstances, anticoagulation may be stopped altogether; in others, patients can proceed to surgery while on anticoagulant therapy or bridging therapy with heparin may be necessary. Urologists must therefore be aware of the intricacies of these issues and be prepared to discuss them with their patients to provide optimal care.

SECTION 2
Percutaneous Renal Surgery

CHAPTER 6

Surgical Anatomy of the Kidney in the Prone, Oblique, and Supine Positions

Francisco J. B. Sampaio

State University of Rio de Janeiro; and National Council for Scientific and Technological Development – CNPq, Rio de Janeiro, Brazil

General anatomy

The kidneys are paired organs lying retroperitoneally on the posterior abdominal wall. Each kidney has a characteristic shape, with a superior and an inferior pole, a convex border placed laterally, and a concave medial border. The medial border has a marked depression, the hilum, containing the renal vessels and renal pelvis.

Renal morphometry

In adults, the left kidney is larger than the right, and this agrees withmorphometric findings in fetal kidneys [1]. The right kidney has a mean length of 10.97 cm and 3.21 cm mean thickness at the hilum, in comparison to 11.21 cm and 3.37 cm, respectively, for the left kidney [2].

An interesting finding is that the superior pole has a greater width (mean, 6.48 cm) than the inferior pole (mean, 5.39 cm). Also, we have found a statistically significant correlation between kidney length and an individual's stature [2].

Position of the kidneys

Because the kidneys lie on the posterior abdominal wall, against the psoas major muscles, their longitudinal axis parallels the oblique course of the psoas (Figure 6.1). Moreover, since the psoas major muscle has a cone shape, the kidneys also are dorsally inclined on the longitudinal axis. Therefore, the superior poles are more medial and more posterior than the inferior poles (Figure 6.1). Also, because the hilar region is rotated anteriorly on the psoas muscle, the lateral borders of both kidneys are posteriorly positioned. This means the kidneys are angled 30–50° behind the frontal (coronal) plane (Figure 6.2) [3].

Perirenal coverings

The kidney surface is enclosed in a continuous covering of fibrous tissue, the renal capsule ("true renal capsule"). Each kidney within its capsule is surrounded by a mass of adipose tissue, lying between the peritoneum and the posterior abdominal wall (Figures 6.2 and 6.3). This perirenal fat is enclosed by the renal fascia (the so-called fibrous renal fascia of Gerota). The renal fascia is enclosed anteriorly and posteriorly by another layer of adipose tissue, the pararenal fat, which varies in thickness (Figure 6.3).

The renal fascia is made up of a posterior layer (a well defined and strong structure) and an anterior layer (a more delicate structure, which tends to adhere to the peritoneum) (Figures 6.2 and 6.3). The anterior and posterior layers of the renal fascia (fascia of Gerota) subdivide the retroperitoneal space into three potential compartments: (1) the posterior pararenal space, which contains only fat; (2) the intermediate perirenal space, which contains the suprarenal glands, kidneys, and proximal ureters, together with the perirenal fat; and (3) the anterior pararenal space, which unlike the posterior and intermediate spaces, extends across the midline from one side of the abdomen to the other. This latter space contains the ascending and descending colon, the duodenal loop, and the pancreas [3] (Figure 6.4).

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Inferiorly, the layers of the renal fascia end weakly fused around the ureter (Figures 6.3 and 6.5). Superiorly, the two layers of the renal fascia fuse above the suprarenal gland and end fused with the infradiaphragmatic fascia (Figure 6.5). An additional fascial layer separates the suprarenal gland from the kidney (Figure 6.5). Laterally, the two layers of the renal fascia fuse behind the ascending and descending colons. Medially, the posterior fascial layer is fused with the fascia of the spine muscles. The anterior fascial layer merges into the connective tissue of the great vessels (aorta and inferior vena cava) (Figures 6.2 and 6.4).

These anatomic descriptions of the renal fascia show that the right and left perirenal spaces are potentially separated and, therefore, it is exceptional that a complication of an endourologic procedure, e.g. hematoma, urinoma, or perirenal abscess, involves the contralateral perirenal space [3].

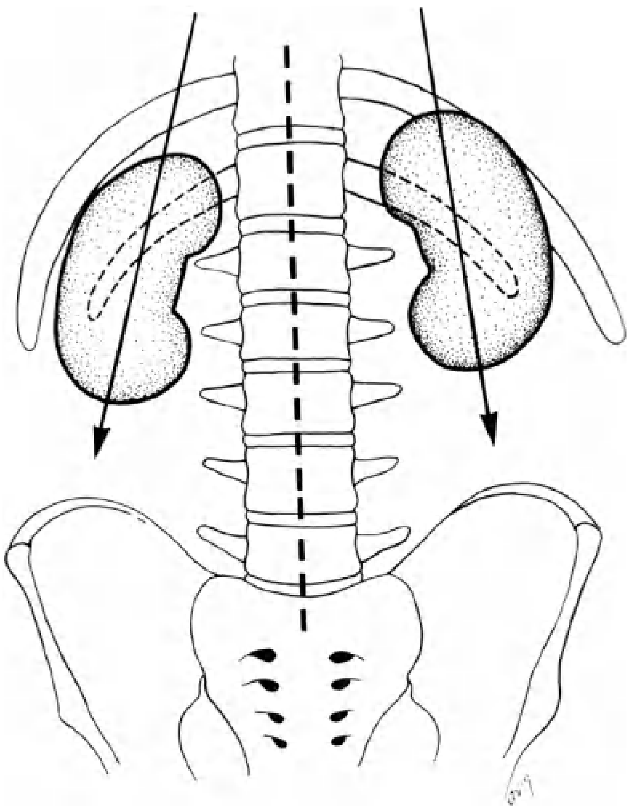

Figure 6.1 Schematic of an anterior view of the kidneys in relation to the skeleton showing that the longitudinal axes of the kidneys are oblique (arrows), with the superior poles more medial than the inferior poles. The dashed lines mark the longitudinal axis of the body. It can also be seen that usually the posterior surface of the right kidney is crossed by the 12th rib and the left kidney by the 11th and 12th ribs.

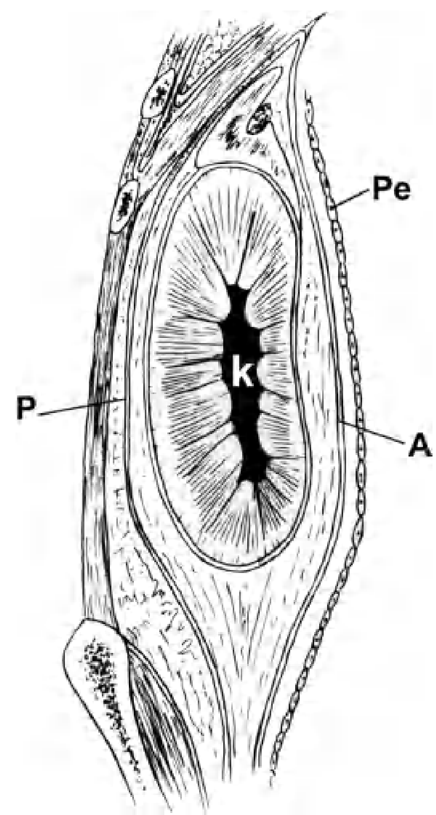

Figure 6.3 Schematic of a lateral view of a longitudinal section through the retroperitoneum showing the posterior (P) and anterior (A) layers of the renal fascia. Pe, peritoneum; K, kidney.

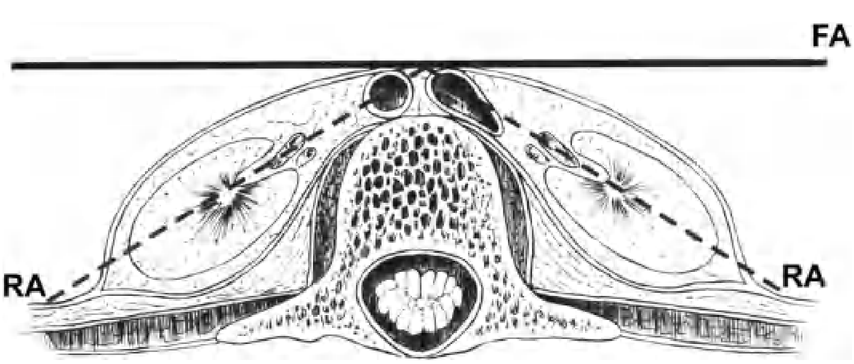

Figure 6.2 Schematic of a superior view of a transverse section of the kidneys at the level of the second lumbar vertebra showing that the kidneys are angled 30–50° behind the frontal (coronal) plane of the body (FA). RA, renal frontal (coronal) axis.

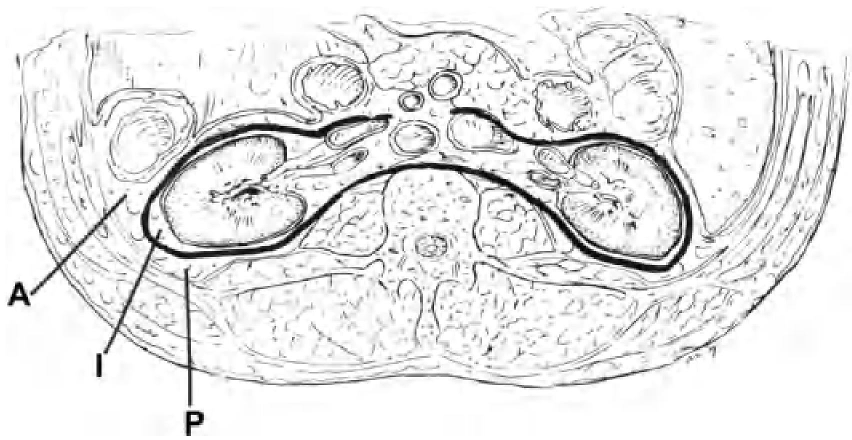

Figure 6.4 Schematic of a superior view of a transverse section of the kidneys at the level of the second lumbar vertebra showing the three compartments of the retroperitoneal space. P, posterior pararenal space, which contains only fat; I, intermediate perirenal space, which contains the suprarenal glands, kidneys, and proximal ureters, together with the perirenal fat; and A, anterior pararenal space, which unlike the posterior and intermediate spaces, extends across the midline from one side of the abdomen to the other, and contains the ascending and descending colons, duodenal loop, and pancreas.

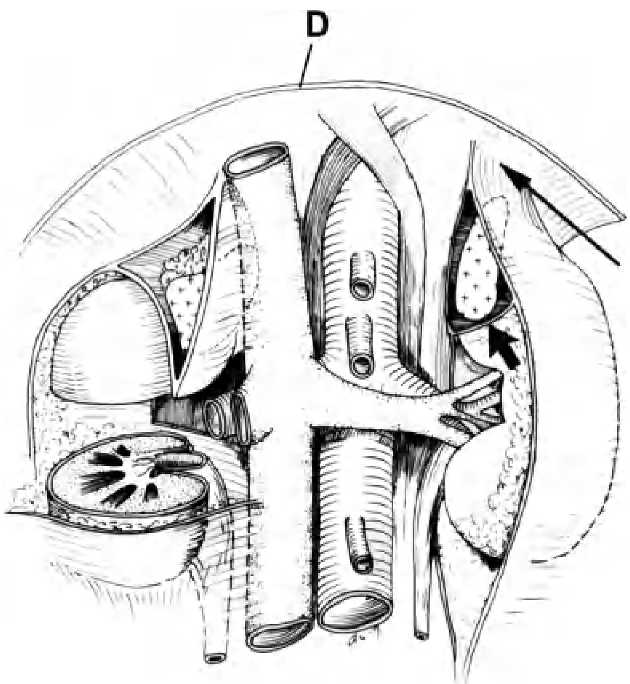

Figure 6.5 Schematic of an anterior view of the renal fascia (Gerotas' fascia) and kidneys. This shows that the two layers of the renal fascia fuse above the suprarenal gland and end fused with the infradiaphragmatic fascia (long arrow). Note a dependence of the fascia separating the suprarenal gland from the kidney (short arrow). D, diaphragm muscle.

Relationship of kidneys to the diaphragm, ribs, and pleura

The kidneys lie on the psoas and quadratus lumborum muscles. Usually, the left kidney is higher than the right kidney, with the posterior surface of the right kidney crossed by the 12th rib and the left kidney crossed by the 11th and 12th ribs (Figure 6.1). The posterior surface of the diaphragm attaches to the extremities of the 11th and 12th ribs (Figure 6.6). Close to the spine, the diaphragm is attached over the posterior abdominal muscles, and forms the medial and lateral arcuate ligaments on each side (Figure 6.6). In this way, the posterior aspect of the diaphragm (posterior leaves) arches in a dome above the superior pole of the kidneys, on each side. Therefore, when performing an intrarenal access by puncture, the endourologist may consider that the diaphragm is traversed by all intercostal punctures, and possibly by some punctures below the 12th rib (Figure 6.7). Also, it can be expected that the pleura is transversed without symptoms in most intercostal approaches [4].

Generally, the posterior reflection of the pleura extends inferiorly to the 12th rib; nevertheless, the lowermost lung edge lies above the 11th rib (at the 10th intercostal space) (Figure 6.7). Regardless of the degree of respiration (mid or full expiration), the risk of injury to the lung from a 10th intercostal percutaneous approach to the kidney is prohibitive [4]. Any intercostal puncture should be made in the lower half of the intercostal space, in order to avoid injury to the intercostal vessels above.

Relationship of kidneys to the liver and spleen

The liver on the right side and the spleen on the left may be posterolaterally positioned at the level of the suprahilar region of the kidney, because at this point these organs have their largest dimensions (Figure 6.8). Therefore, it should be remembered that a kidney puncture performed high in the abdomen will allow little space for the needle entrance [4]. If the intrarenal puncture is performed when the patient is in mid or full inspiration, the risk of injury to the liver and spleen is increased [4]. This knowledge is particularly important in patients with hepatomegaly or splenomegaly, in whom a computed tomography (CT) scan should be performed before puncturing the kidney.

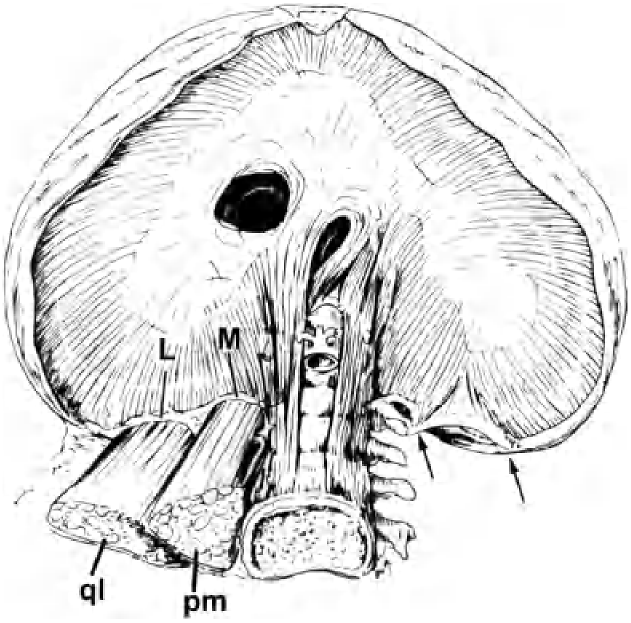

Figure 6.6 Schematic of an inferior view of the diaphragmatic dome. The arrows point to the diaphragmatic attachments to the extremities of the 11th and 12th ribs. M, medial arcuate ligament; L, lateral arcuate ligament; ql, quadratus lumborum muscle; pm, psoas muscle.

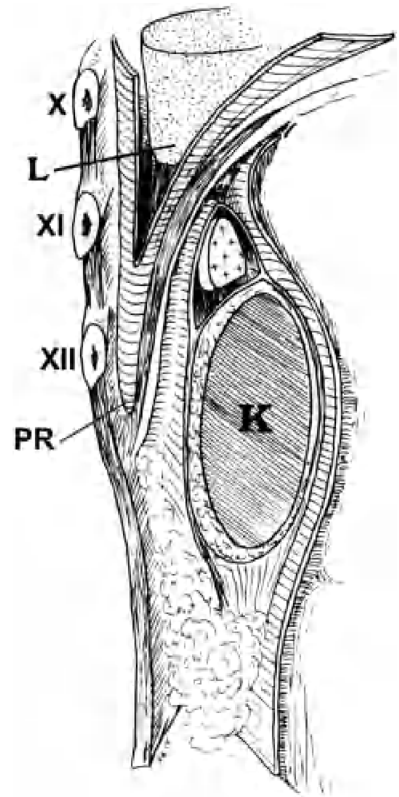

Figure 6.7 Schematic of a lateral view of the kidney and its relationships with the diaphragm, ribs, pleura, and lung. PR, posterior reflection of the pleura, L, lower edge of the lung; K, kidney; X, 10th rib; XI, 11th rib; XII 12th rib.

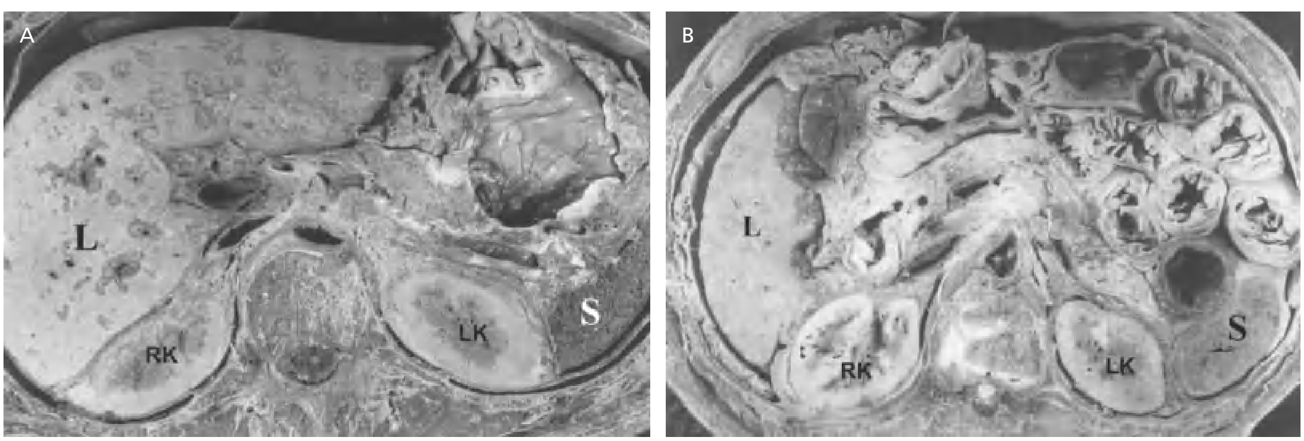

Figure 6.8 (A) Inferior view of a transverse section through a cooled cadaver at the level of the suprahilar region of the kidney. This shows that the liver (L) and spleen (S) are posterolaterally positioned in relation to the right (RK) and left (LK) kidneys. (B) Similar section to A at the level of the infrahilar region. This shows that inferiorly the liver (L) and spleen (S) are more laterally positioned in relation to the right (RK) and left (LK) kidneys.

Relationship of kidneys to the ascending and descending colons

The ascending colon runs from the ileocolic valve to the right colic flexure (hepatic flexure), where it passes into the transverse colon. The hepatic colic flexure (hepatic angle) lies anteriorly to the inferior portion of the right kidney. The descending colon extends inferiorly from the left colic flexure (splenic flexure) to the level of the iliac crest. The left colic flexure lies anterolateral to the left kidney.

It is important to consider the position of the retroperitoneal ascending and descending colons. Occasionally, in

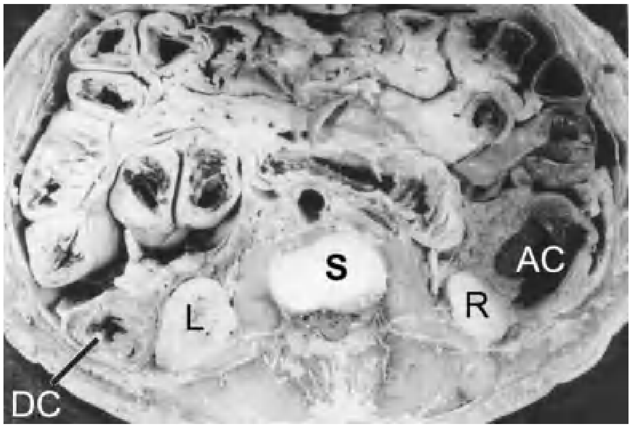

Figure 6.9 Superior view of a transverse section through a cooled cadaver at the level of the inferior poles of the kidney. This shows the ascending (AC) and descending (DC) colons lying in a posterolateral position in relation to the right (R) and left (L) kidneys. S, spine.

the course of a routine abdominal CT scan, the retroperitoneal colon has been observed to lie in a posterolateral or even a retrorenal position [5], and in these cases, there is a great risk of kidney injury with the intrarenal percutaneous approach. A retrorenal colon is more common in the area of the inferior poles of the kidneys (Figure. 6.9). It Retrorenal colon was found on CT scan in 1.9% of patients in the supine position, but 10% when the prone position (the more commonly adopted position for percutaneous access to the kidney) was assumed [5]. Therefore, with the patient in the prone position and before any invasive percutaneous renal procedure, retrorenal colon should be looked for, especially around the inferior poles of the kidney, using fluoroscopy [5].

Intrarenal vessels

Intrarenal arteries

Generally, the main renal artery divides into an anterior and a posterior branch after giving off the inferior suprarenal artery. Whereas the posterior branch (retropelvic artery) proceeds as the posterior segmental artery to supply the homonymous segment without further significant branching, the anterior branch of the renal artery provides three or four segmental arteries. The segmental arteries divide before entering the renal parenchyma into the interlobar arteries (infundibular arteries), which progress adjacent to the calyceal infundibula and the minor calyces, entering the renal columns between the renal pyramids (Figures 6.10 and 6.11) [6]. As the interlobar arteries progress, near the base of the pyramids, they give origin (usually by

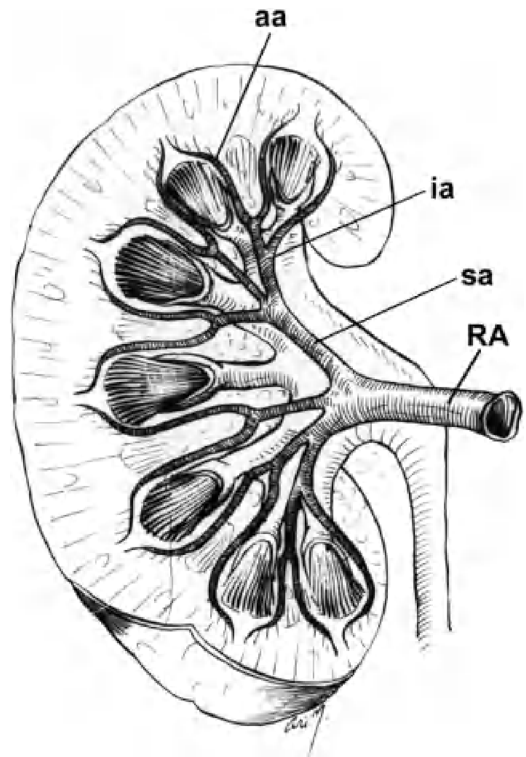

Figure 6.10 Schematic of an anterior view of a right kidney. This shows the branching of the renal arteries and their official nomenclature according to kidney region. RA, renal artery; sa, segmental artery; ia, interlobar (infundibular) artery; aa, arcuate artery.

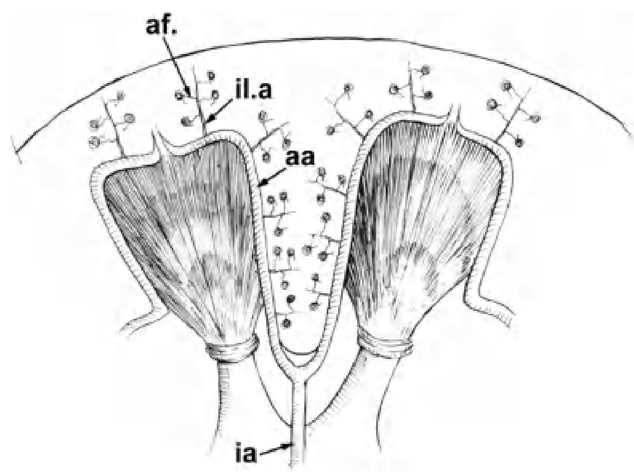

Figure 6.11 Schematic of two adjacent pyramids and minor calyces. This shows the renal vasculature from the level of the interlobar arteries to the glomerular level. ia, interlobar (infundibular artery); aa, arcuate artery; il.,, interlobular artery; af., afferent arteriole of the glomerulus.

dichotomous division) to the arcuate arteries (Figures 6.10 and 6.11). The arcuate arteries give off the interlobular arteries, which run to the periphery, giving off the afferent arterioles of the glomeruli (Figure 6.11) [6].

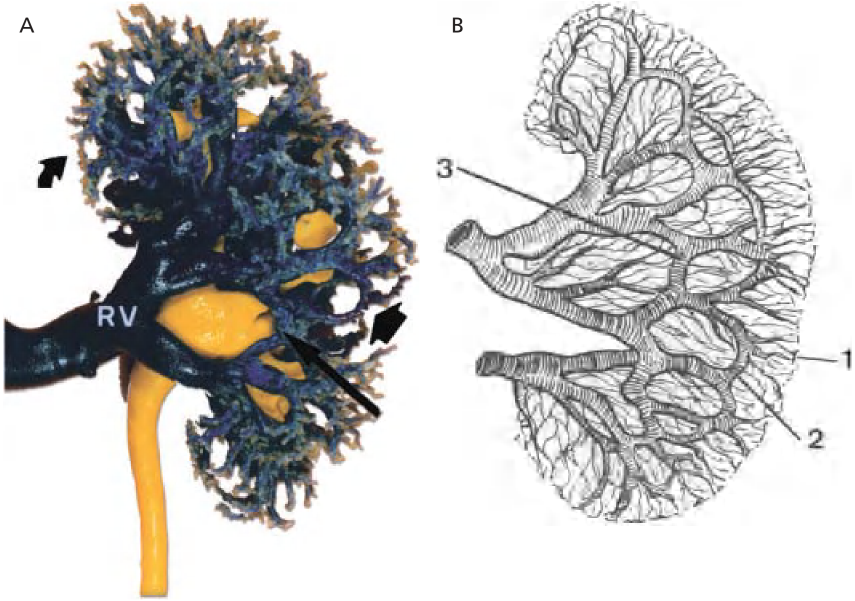

Figure 6.12 (A) Anterior view of a left kidney endocast of the pelviocalyceal system together with the venous vascular tree. This shows the three systems of longitudinal anastomotic arcades; from lateral (periphery) to medial (hilar): stellate veins (curved arrow), arcuate veins (short arrow), and interlobar veins (long arrow). RV, renal vein. (B) Schematic showing the three orders of arcades: 1, first order arcade; 2, second order arcade; 3, third order arcade.

Intrarenal veins

The intrarenal veins, unlike the arteries, do not have a segmental model. Moreover, in contrast to the arteries, there is free circulation throughout the venous system, with ample anastomoses between the veins. These anastomoses, therefore, prevent parenchymal congestion and ischemia in case of venous injury [7].

The small veins of the cortex, called stellate veins, drain into the interlobular veins that form a series of arches (Figure 6.12). Within the kidney substance, these arches are arranged in arcades, which lie mainly in the longitudinal axis. There are usually three systems of longitudinal anastomotic arcades and the anastomoses occur at different levels: between the stellate veins (more peripherally), between the arcuate veins (at the base of the pyramids), and between the interlobar (infundibular) veins (close to the renal sinus) (Figure 6.12). We have named these anastomoses as first order, second order, and third order, from periphery to center [7]. In early studies, we found three trunks (53.8%) and two trunks (28.8%) joining each other to form the main renal vein. Less frequently, we found four trunks (15.4%) and five trunks (1.9%) [7].

A detailed description of the kidney collecting system (the pelviocalyceal system), as well as the anatomic relationships between the intrarenal arteries and veins with the kidney collecting system, which are of utmost importance for endourology, is given below.

Pelvicocalyceal system: endourologic implications

Anatomic classification

Recent advances in endourology have revived interest in collecting system anatomy, since a full understanding of such anatomy is necessary to perform reliable endourologic procedures as well as uroradiologic analysis [8–10]. We have proposed a pelviocalyceal classification, including all morphologic types of collecting systems, which we believe is helpful for standardizing patients and procedures [9]. This classification was derived from the analysis of 140 three-dimensional (3D) polyester resin corrosion endocasts of the pelviocalyceal system (Figure 6.13), obtained from 70 fresh cadavers according to a technique described previously [8].

Basic intrarenal anatomy

The renal parenchyma basically consists of two kinds of tissue, the cortical tissue and medullar tissue. On a longitudinal section (Figure 6.14), the cortex forms the external layer of renal parenchyma. The renal medulla is formed by several inverted cones, surrounded by a layer of cortical tissue on all sides (except at the apices). As in longitudinal sections, a cone assumes the shape of a pyramid (Figure 6.14) and the established term for the medullar tissue is renal pyramid; the apex of this pyramid is termed the renal papilla. The layers of cortical tissue between adjacent pyramids are termed renal columns (cortical columns of Bertin; Figure 6.14) [8, 10].

The cortical tissue is made up of the glomeruli with proximal and distal convoluted tubules. The renal pyramids are made up of loops of Henle and collecting ducts; these ducts join to form the papillary ducts (about 20), which open at the papillary surface (area cribosa; Figure 6.15) and drain urine into the collecting system (into the fornix of a minor calyx).

A minor calyx is defined as the calyx that is in immediate apposition to a papilla (Figures 6.14 and 6.15). The renal minor calyces drain the renal papillae and range

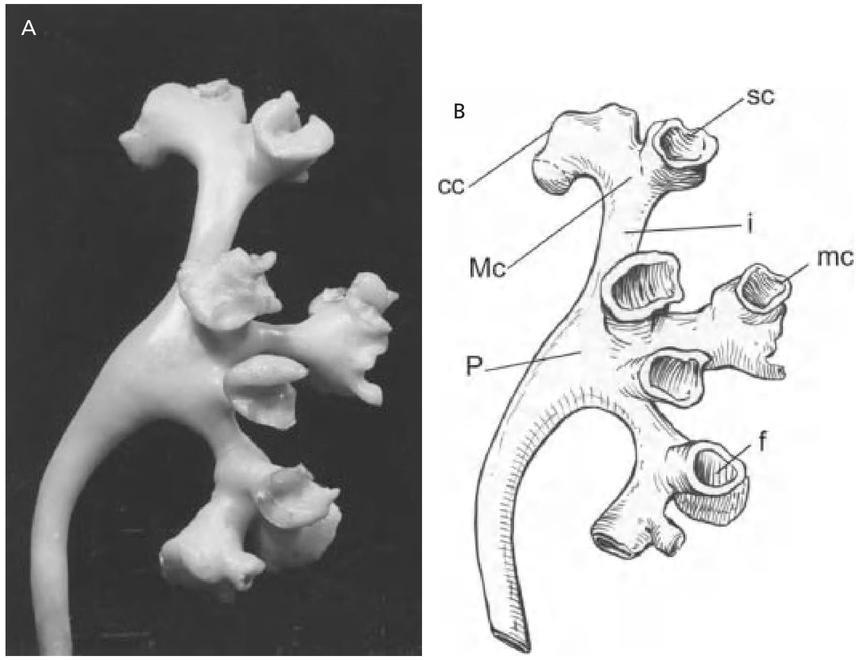

Figure 6.13 (A) Anterior view of a pelviocalyceal endocast from a left kidney, obtained according to the injection–corrosion technique. (B) Schematic of the endocast shown in A. This shows the essential elements of the kidney collecting system. cc, compound calyx; sc, single calyx; mc, minor calyx; Mc, major calyx; f, calyceal fornix; i, infundibulum; P, renal pelvis (Renal Anatomy Applied to Urology, Endourology, and Interventional Radiology, Sampaio FJB, Uflacker R, eds., Thieme, 1993 (reprinted with permission)).

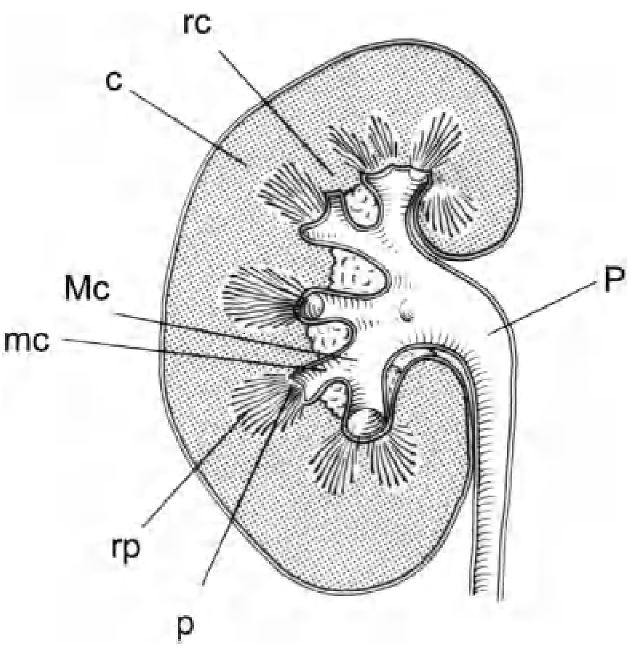

Figure 6.14 Schematic of a longitudinal section of the kidney. Figure 6.15 Schematic representation of the possible minor calyx (mc) arrangements. A single mc drains only one papilla and a compound mc drains two or three papillae. p, renal papilla; pd, papillary ducts; ac, area cribosa; Mc, major calyx; imc, infundibulum of a mc (calyceal neck); i, infundibulum (Renal Anatomy Applied to Urology, Endourology, and Interventional Radiology, Sampaio FJB, Uflacker R, eds., Thieme, 1993 (reprinted with permission)).

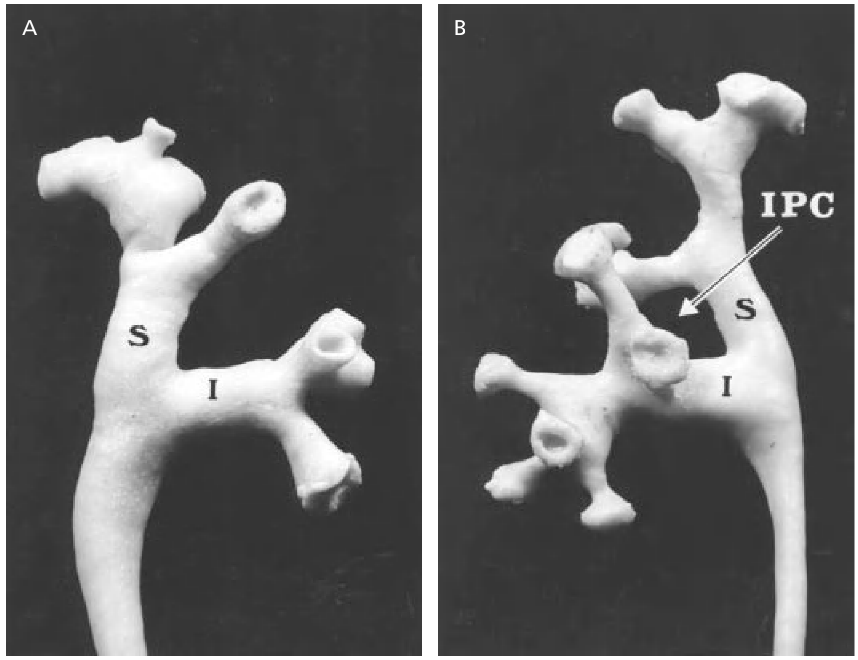

Figure 6.16 View of the two morphologic types of pelviocalyceal systems that compose Group A. (A) Type A-I: anterior view of a left pelviocalyceal endocast shows the kidney midzone drained by calyces dependent on the superior (S) and inferior (I) calyceal groups. (B) Type A-II: anterior view of a right pelviocalyceal cast shows the kidney midzone drained by crossed calyces, dependent simultaneously on the superior (S) and inferior (I) calyceal group. This endocast shows the interpelviocalyceal space (IPC) (Renal Anatomy Applied to Urology, Endourology, and Interventional Radiology, Sampaio FJB, Uflacker R, eds., Thieme, 1993 (reprinted with permission)).

in number from 5 to 14 (mean, 8); we have found 70% of kidneys to have 7–9 minor calyces [8]. A minor calyx may be single (drains one papilla) or compound (drains two or three papillae) (Figures 6.13 and 6.15). The polar calyces are often compound, markedly in the superior pole (Figure 6.13). The minor calyces may drain straight into an infundibulum or join to form major calyces, which subsequently will drain into an infundibulum (Figures 6.13 and 6.15). Finally, the infundibula, which are considered the primary divisions of the pelviocalyceal system, drain into the renal pelvis.

Classification of the pelviocalyceal system

The analysis of 140 endocasts led us to a division into two major groups (with two intermediate varieties in each major group). This division was based on superior pole, inferior pole, and kidney midzone (hilar) calyceal drainage.

Group A is composed of pelviocalyceal systems that have two major calyceal groups (superior and inferior) as a primary division of the renal pelvis and a midzone calyceal drainage dependent on these two major groups (62.2%) (Figure 6.16). Group A includes two different types of pelviocalyceal system:

- Type A-I (45%). The kidney midzone is drained by minor calyces that are dependent on the superior and/or inferior calyceal groups (Figure 6.16A).
- Type A-II (17.2%). The kidney midzone is drained simultaneously by crossed calyces, one draining into the superior calyceal group and the other draining into the inferior calyceal group (Figure 6.16B). When we analyzed the endocasts with crossed calyces in the kidney midzone, we observed that the crossed calyces (laterally) and the renal pelvis (medially) bound a region (space) that we designated the "interpelviocalyceal" (IPC) region (space) (Figure 6.16B).

Group B is composed of pelviocalyceal systems with kidney midzone (hilar) calyceal drainage independent of both the superior and inferior calyceal groups (37.8%) (Figure 6.17). This group also includes two different types of pelviocalyceal system:

- Type B-I (21.4%). The kidney midzone is drained by a major calyceal group, independent of both the superior and the inferior groups (Figure 6.17A).
- Type B-II (16.4%). The kidney midzone is drained by minor calyces (one to four) entering directly into the renal pelvis (Figure 6.17B). Such calyces are independent of both the superior and inferior calyceal groups.

The kidney collecting system is very variable and is not symmetrical. We found pelviocalyceal systems with morphologic bilateral symmetry in the same individual in only 37.1% of the cases (26 pairs of kidneys).

Although our pelviocalyceal classification includes all morphologic types of calyces and renal pelvices, in performing endourologic procedures it is important to be aware that the collecting system anatomy is very variable. The endocast in Figure 6.18A, for example, reveals a very long and thin superior calyceal infundibulum;

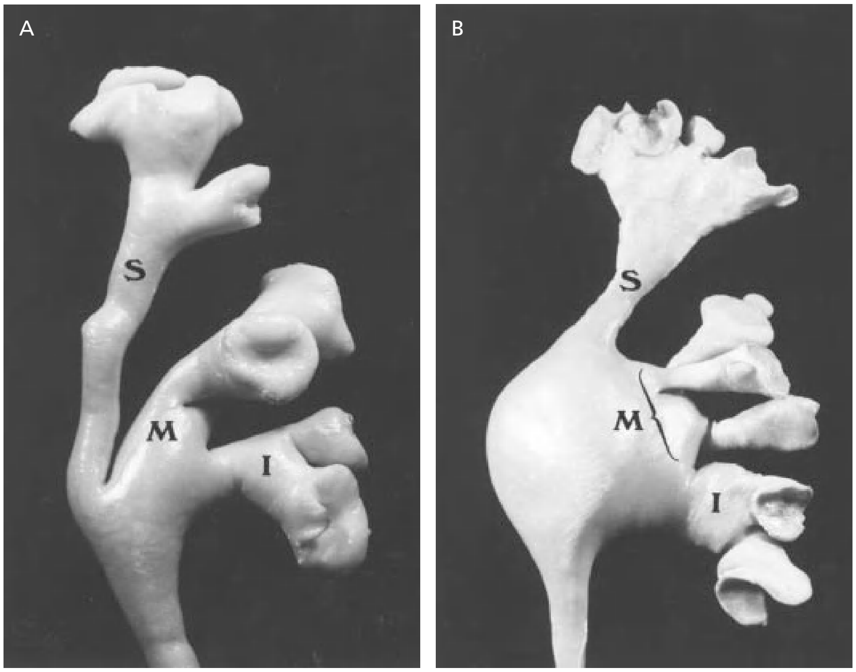

Figure 6.17 View of the two morphologic types of pelviocalyceal systems that compose Group B. (A) Type B-I: anterior view of a left pelviocalyceal endocast shows the kidney midzone drained by a hilar major calyx (M), independently of the superior (S) and inferior (I) major calyces. (B) Type B-II: anterior view of a left pelviocalyceal endocast shows the kidney midzone drained by minor calyces (M) entering directly into the renal pelvis, independently of both the superior (S) and inferior (I) calyceal groups (Renal Anatomy Applied to Urology, Endourology, and Interventional Radiology, Sampaio FJB, Uflacker R, eds., Thieme, 1993 (reprinted with permission)).

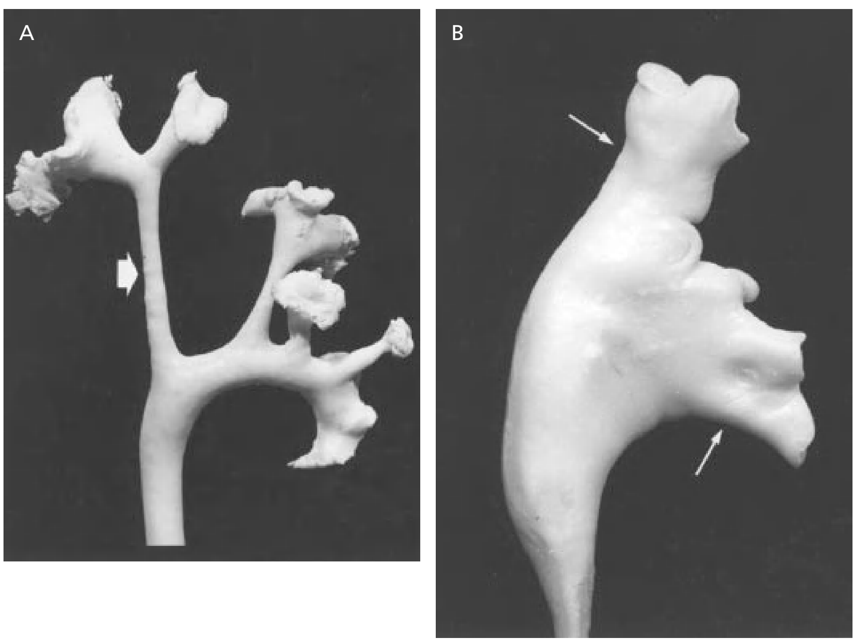

Figure 6.18 Anterior view of two left pelviocalyceal endocasts, one showing a long and thin superior calyceal infundibulum (arrow) (A) and the other a short and thick superior and inferior calyceal infundibula (arrows) (B) (Renal Anatomy Applied to Urology, Endourology, and Interventional Radiology, Sampaio FJB, Uflacker R, eds., Thieme, 1993 (reprinted with permission)).

this anatomic formation will certainly cause difficulties in the introduction and manipulation of a nephroscope into the superior pole collecting system. The endocast in Figure 6.18B shows just the opposite aspect (both superior and inferior calyceal infundibula are short and thick); this anatomic formation will certainly make it easier to introduce and manipulate a nephroscope within the superior and inferior collecting systems.

Comparative analysis between standard pyelograms and the corresponding three-dimensional collecting system endocasts

Since standard excretory urograms [intravenous pyelograms (IVPs)] show the collecting system in only one plane, it is extremely difficult for the practitioner to visualize and imagine this system in three dimensions.

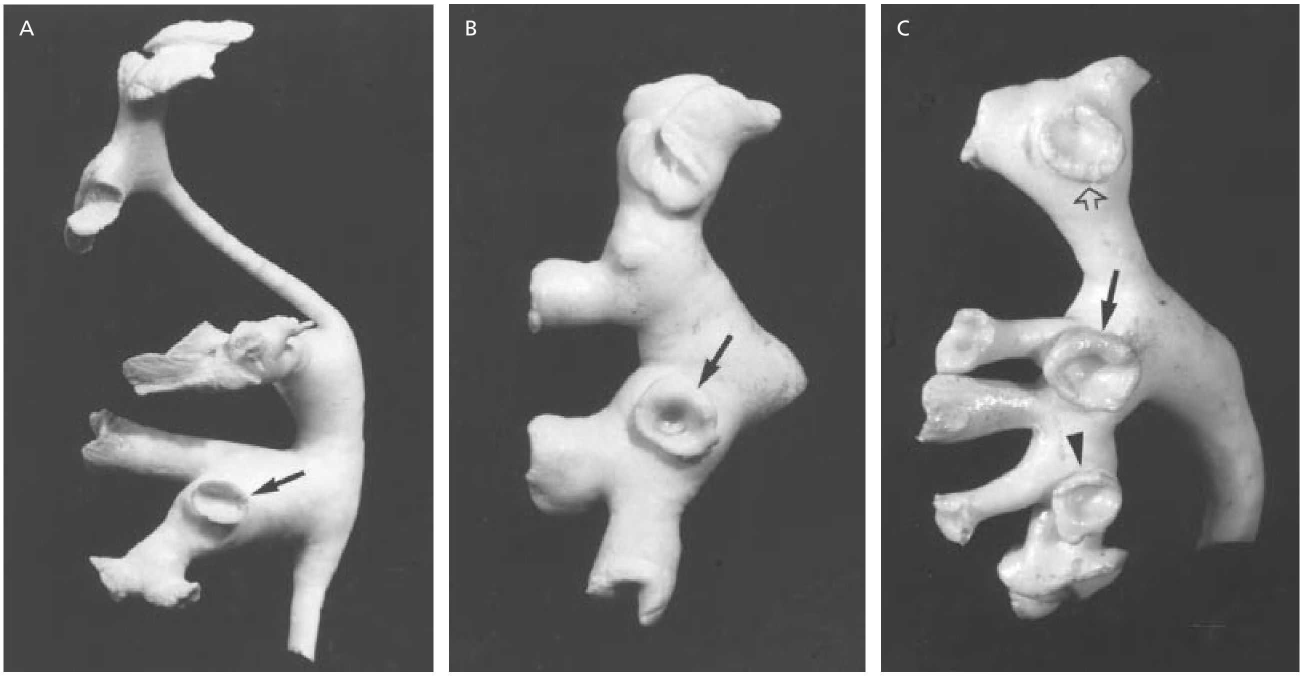

Figure 6.19 Anterior views of a right pelviocalyceal endocast showing (A) a perpendicular minor calyx draining into the inferior calyceal group (arrow); (B) into the inferior calyceal group (arrow), very close to the renal pelvis; and (C) into the renal pelvis (arrow). This latter endocast also shows a perpendicular minor calyx draining into the superior calyceal group (open arrow) and a perpendicular minor calyx draining into the inferior calyceal group (arrowhead) (Renal Anatomy Applied to Urology, Endourology, and Interventional Radiology, Sampaio FJB, Uflacker R, eds., Thieme, 1993 (reprinted with permission)).

A full understanding of pelviocalyceal anatomy is a prerequisite for successful endourologic interventions in the upper urinary tract, as well as for interpreting IVPs and other imaging examinations.

To assist endourologists in forming a mental image of the collecting system in three dimensions and learning the exact spatial position of the calyces, before obtaining the pelviocalyceal system endocast, iodinated contrast was injected into the ureter of 40 of our cases to opacify the collecting system in order to obtain a pyelogram. After radiography, the contrast was removed and the collecting system was filled with a polyester resin to obtain a 3D endocast. These 40 kidneys enabled a comparative study between the radiographic images and their corresponding 3D endocasts. This identified some remarkable anatomic aspects of the kidney collecting system that need to be considered during endourologic procedures.

Presence of perpendicular minor calyces

In 11.4% of the endocasts (16 of 140) we found a perpendicular minor calyx draining directly into the renal pelvis or into a major calyx (Figure 6.19). The minor calyces perpendicular to the surface of the collecting system, which are seen in the endocasts, can be superimposed on other structures, which means their visualization radiographically can be difficult (Figure 6.20). Stones in such minor calyces viewed on standard anteroposterior radiographic images can appear as if they were placed in the pelvis or a major calyx. Thus, this anatomic detail must be considered in cases of stones that do not alter renal function and can appear as if they are in the renal pelvis or a major calyx. In this situation, a complementary radiologic study with lateral and oblique films must be performed to determine accurately the position and extent of the stones [11, 12].

When a stone is located in a perpendicular minor calyx (Figure 6.19), its removal presents additional difficulties for both extracorporeal shock-wave lithotripsy (ESWL) and percutaneous nephrolithotripsy (PCNL). Patients with stones in such calyces are not good candidates for ESWL because these calyces invariably present narrow infundibula (<4 mm in diameter); therefore, discharge of the disintegrated stone fragments will be difficult [13, 14]. Regarding percutaneous removal, direct access into the calyx containing the stone is easy; nevertheless, it involves a puncture without consideration of the arterial and venous anatomic relationships to the collecting system, which carries a high risk of injuring a vascular structure [12]. Therefore, in cases of stone in such calyces, safe access, techniques, and instruments should be used.

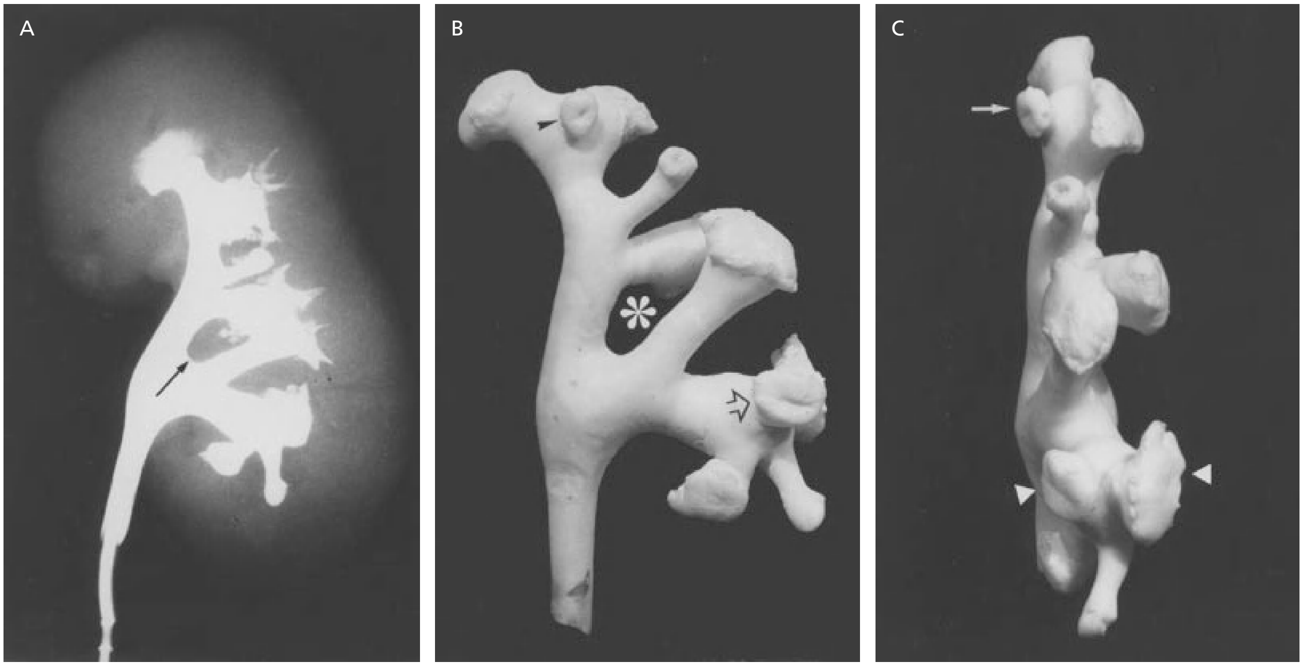

Figure 6.20 Comparative study between radiographic view of a left kidney and its corresponding three-dimensional (3D) endocast. (A) Anterior view of a retrograde pyelogram shows a radiographic image of the interpelviocalyceal region (arrow). (B) Anterior view of the corresponding 3D endocast. The asterisk denotes the interpelviocalyceal space; the arrowhead points to a minor calyx perpendicular to and superimposed on the surface of a superior major calyx, which cannot be seen on the pyelogram; and the open arrow points to an anterior minor calyx superimposed on the posterior minor calyx. It can be difficult to make the distinction between these features on a pyelogram. (C) Oblique view of the same endocast as in B. The arrow points to a perpendicular minor calyx in the superior calyceal group; and arrowheads to the distinction between the anterior and posterior minor calyces, which are superimposed on the pyelogram (Renal Anatomy Applied to Urology, Endourology, and Interventional Radiology, Sampaio FJB, Uflacker R, eds., Thieme, 1993 (reprinted with permission)).

Crossed calyces

In 17.2% of the endocasts, the kidney midzone (hilar) was drained simultaneously by crossed calyces, one draining into the superior calyceal group and the other into the inferior calyceal group. On the pyelograms, the crossed calyces (laterally) and the renal pelvis (medially) outlined a radiotransparent region that we termed the interpelviocalyceal region (Figure 6.20A). In the 3D endocasts, that same region appeared as a space (Figure 6.20B) [9, 11, 12].

The interpelviocalyceal space may have different shapes: lozenge-like (the most common), long and narrow, and even small and round, depending on the shape of the calyces and the shape of the renal pelvis (Figure 6.21). Regardless of the form assumed by the interpelviocalyceal space, it is the result of crossed calyces in the mid kidney.

When the crossed calyces were in the mid kidney, the calyx draining into the inferior calyceal group was in the ventral position in 87.5% of the endocasts [9, 11, 12] (Figure 6.22). In some cases, even when radiographically the calyx draining into the inferior group was apparently in the dorsal position, we verified its ventral position on the endocast (Figure 6.22). This constant spatial arrangement is noteworthy for endourologic maneuvers. If the intention is to access the renal pelvis via a crossed calyx or to access a crossed calyx via the renal pelvis, it is useful to remember that the calyx draining into the inferior calyceal group is almost always in the ventral position. It is also worthy of remark that detection of an interpelviocalyceal region on the pyelograms is an indirect sign of crossed calyces in the kidney midzone.

Position of the calyces relative to the lateral kidney margin

In 39 of the 140 endocasts (27.8%), the anterior calyces had a more lateral (peripheral) position than the posterior calyces (Figure 6.23). In 27 endocasts (19.3%), the posterior calyces were in a more lateral position than the anterior calyces (Figure 6.24). In the majority of the endocasts (74; 52.9%), the anterior and posterior calyces had varied positions: superimposed or alternately distributed (in one region the most lateral were the anterior calyces, and in another, the posterior calyces) (Figure 6.25).

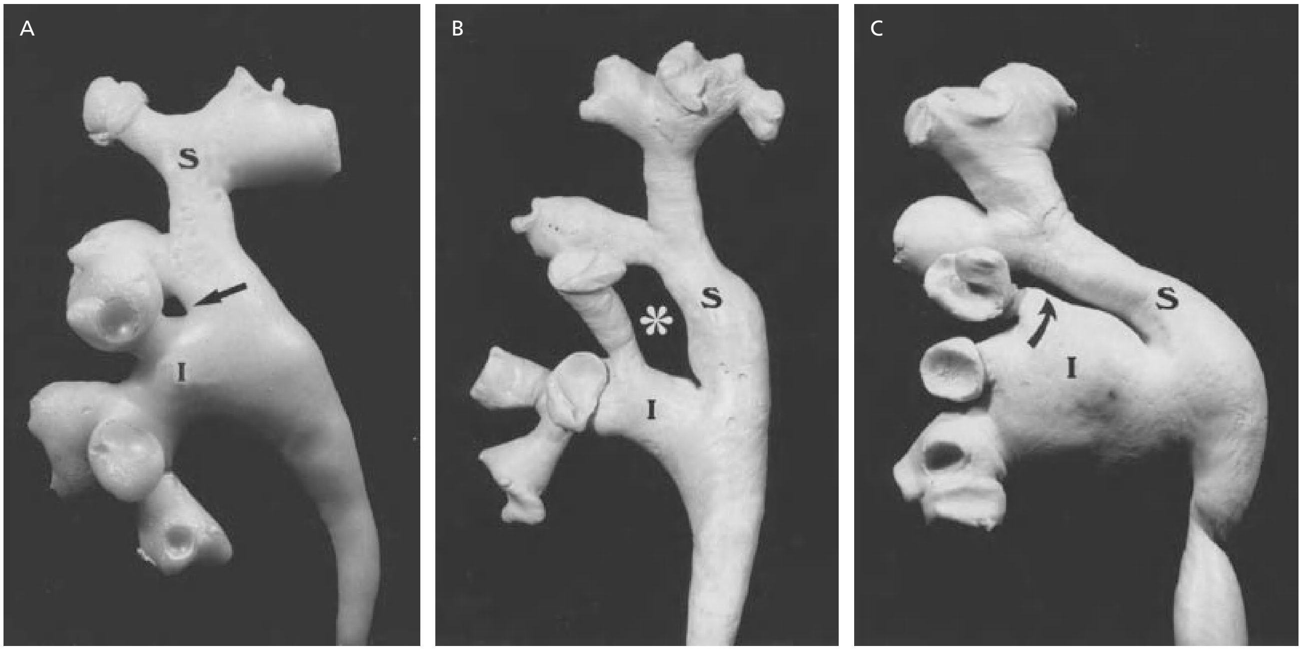

Figure 6.21 Anterior view of right pelviocalyceal endocasts. This shows the different shapes that the interpelviocalyceal (IPC) space may assume: (A) small and round IPC space (arrow); (B) lozenge-like IPC space (most common shape) (asterisk); (C) long and narrow IPC space (curved arrow). S, superior calyceal group; I, inferior calyceal group (Renal Anatomy Applied to Urology, Endourology, and Interventional Radiology, Sampaio FJB, Uflacker R, eds., Thieme, 1993 (reprinted with permission)).

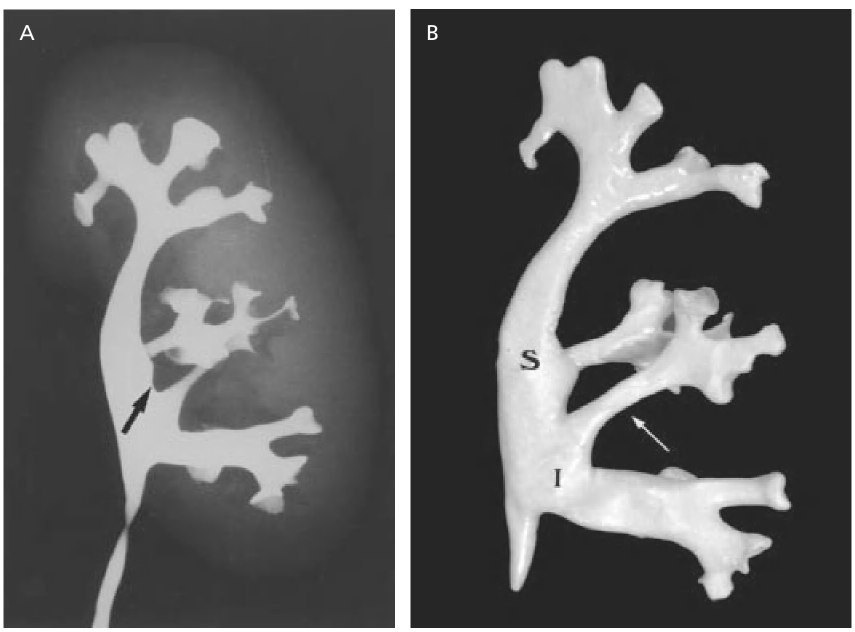

Figure 6.22 Comparative study between a retrograde pyelogram of a left kidney and its corresponding three-dimensional (3D) endocast of the pelviocalyceal system. (A) Anterior view of a retrograde pyelogram shows the radiographic image of the interpelviocalyceal (IPC) region (arrow). (B) Anterior view of the corresponding 3D endocast. The arrow points to the calyx which is draining into the inferior calyceal group in the ventral position (87.7% of the endocasts of the IPC space). S, superior calyceal group; I, inferior calyceal group (Renal Anatomy Applied to Urology, Endourology, and Interventional Radiology, Sampaio FJB, Uflacker R, eds., Thieme, 1993 (reprinted with permission)).

Since the first choice of access to the collecting system is through a posterior calyx, much effort has been made to determine preoperatively which calyces are anterior and which posterior. Previous studies have presented contradictory results and lead to misunderstanding of this subject [15]. We have described the type of kidney collecting system found in the majority of the endocasts, in which the calyces are disposed in various positions (superimposed or alternately distributed), and can affirm that the position of the calyces cannot be defined as more lateral or more medial. Considering the large variation of position of the calyces (>50% in different positions), we believe that precise determination of calyceal position is difficult with the common radiologic

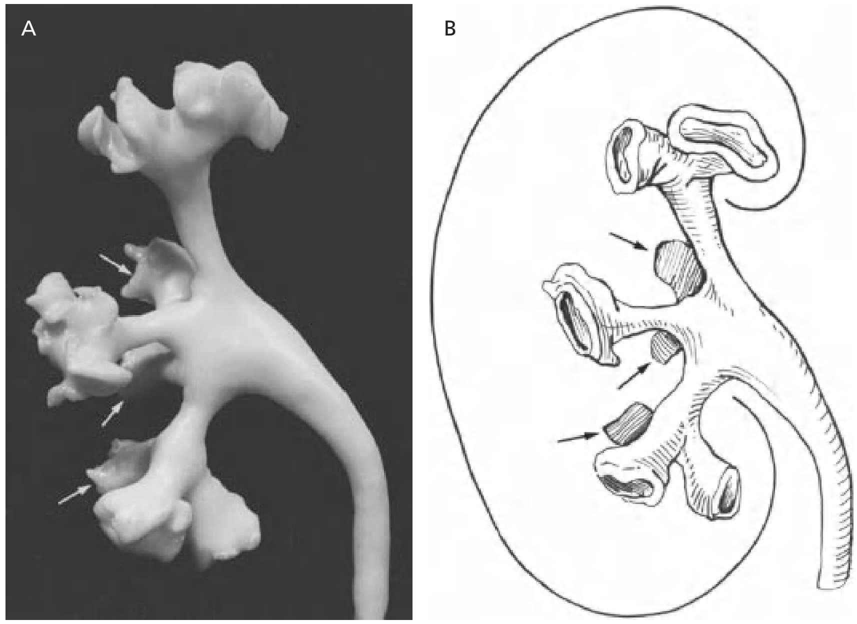

Figure 6.23 Position of the calyces relative to the lateral margin of the kidney. (A) Anterior view of a right pelviocalyceal endocast, which shows the anterior calyces have a more lateral (peripheral) position than the posterior calyces (arrows). This means that the posterior calyces are located medially. (B) Schematic of the endocast shown in A. This shows the peripheral calyces in the anterior plane and the medial calyces (arrows) in the posterior plane (Renal Anatomy Applied to Urology, Endourology, and Interventional Radiology, Sampaio FJB, Uflacker R, eds., Thieme, 1993 (reprinted with permission)).

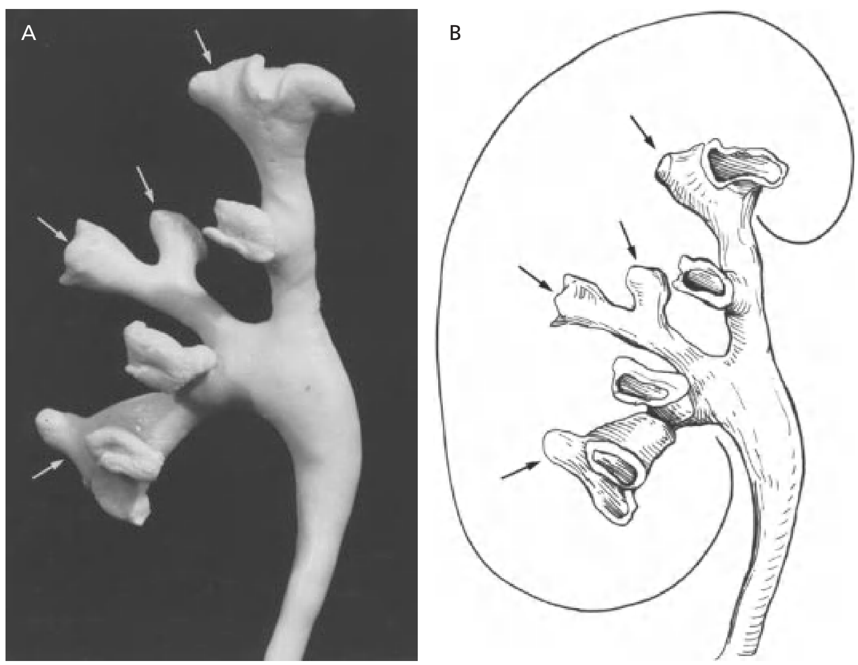

Figure 6.24 Position of the calyces relative to the lateral margin of the kidney. (A) Anterior view of a right pelviocalyceal endocast. This shows that the posterior calyces (arrows) have a more lateral (peripheral) position than the anterior calyces. (B) Schematic of the endocast shown in A. This shows the peripheral calyces in the posterior plane (arrows) and the medial calyces in the anterior plane (Renal Anatomy Applied to Urology, Endourology, and Interventional Radiology, Sampaio FJB, Uflacker R, eds., Thieme, 1993 (reprinted with permission)).

methods, even using oblique and lateral views [9, 11]. To solve this problem quickly and inexpensively, during endourologic procedures, with the patient in the prone position, room air should be injected into the collecting system and this will rise to the more posterior portions of the collecting system, determining which calyces are located posteriorly (radiolucent contrast) [11, 12, 16].

Position of the calyces relative to the polar regions and kidney midzone

The superior pole was drained by a midline calyceal infundibulum in 98.6% of the endocasts (Figure 6.26). The midzone (hilar) was drained by paired calyces that were arranged in two rows (anterior and posterior) in 95.7% of the endocasts (Figure 6.26). The inferior pole

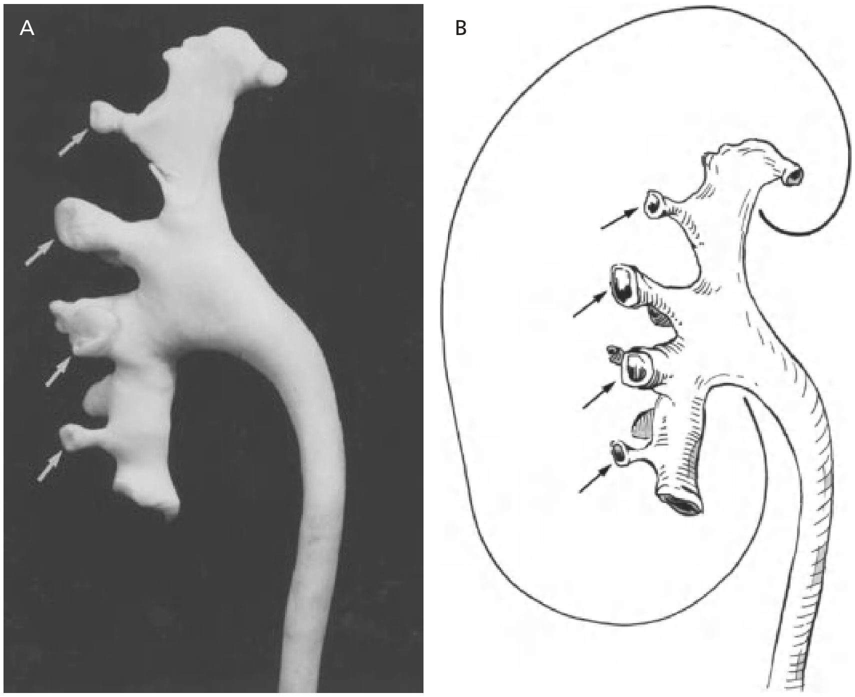

Figure 6.25 Position of the calyces relative to the lateral margin of the kidney. (A) Anterior view of a right pelviocalyceal endocast, and (B) schematic of this endocast. The calyces in the anterior plane (arrows) are located alternately relative to the lateral margin of the kidney, i.e. in one region they are more lateral and in another they are more medial. (Renal Anatomy Applied to Urology, Endourology, and Interventional Radiology, Sampaio FJB, Uflacker R, eds., Thieme, 1993 (reprinted with permission)).

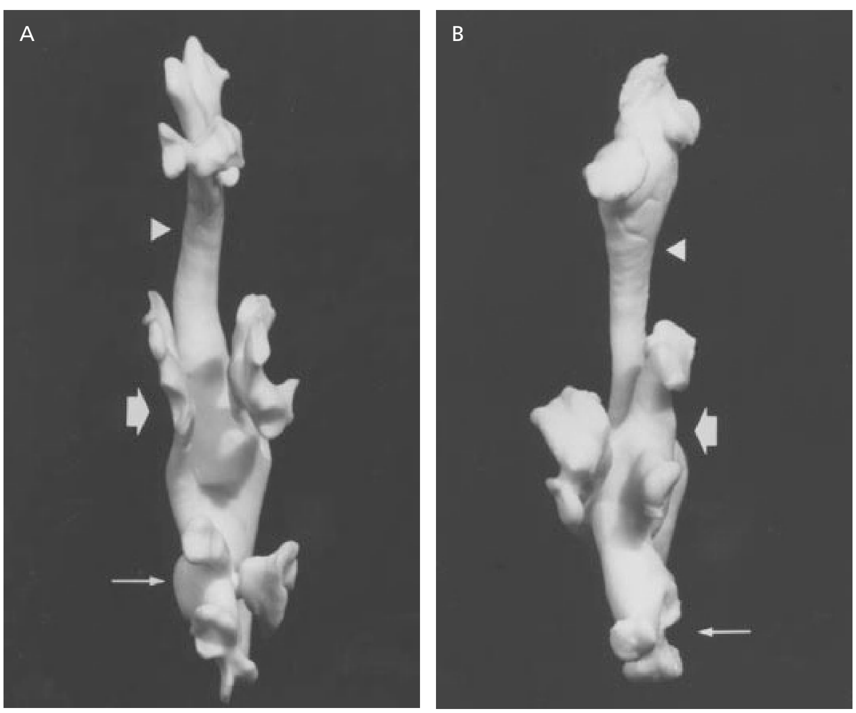

Figure 6.26 Position of calyces relative to the polar regions and kidney midzone. (A) Lateral view of a left pelviocalyceal endocast. The superior pole is drained by a single midline calyceal infundibulum (arrowhead). The midzone (hilar) is drained by paired calyces arranged in two rows (short arrow); anterior and posterior. The inferior pole is drained by paired calyces arranged in two rows (long arrow). (B) Lateral view of a right pelviocalyceal endocast. The superior pole is drained by a single midline calyceal infundibulum (arrowhead). The midzone is drained by paired calyces arranged in two rows (short arrow); anterior and posterior. The inferior pole is drained by only one midline calyceal infundibulum (long arrow) (Renal Anatomy Applied to Urology, Endourology, and Interventional Radiology, Sampaio FJB, Uflacker R, eds., Thieme, 1993 (reprinted with permission)).

was drained by paired calyces arranged in two rows in 81 endocasts (57.9%) (Figure 6.26A) and by a single midline calyceal infundibulum in 59 endocasts (42.1%) (Figure 6.26B).

With regard to the calyceal drainage of the kidney polar regions, many investigators have affirmed that there usually is only one calyceal infundibulum draining each pole [3, 10, 14]. In our study, the superior pole was drained by only one midline calyceal infundibulum in 98.6% of the endocasts. However, the inferior pole was drained by paired calyces arranged in two rows in 81 of the 140 endocasts (57.9%) and by one midline

calyceal infundibulum in 59 endocasts (42.1%) (Figure 6.26). These results are important in endourology; it will be easier to access endoscopically a polar region drained by a single infundibulum, which usually has a suitable diameter, rather than a polar region drained by paired calyces (Figure 6.26). Because the inferior pole is drained by paired calyces in 57.9% of the endocasts, this anatomic detail must be kept in mind, both to plan and perform the intrarenal access and endoscopic procedures in the inferior pole. The calyceal drainage of superior and inferior poles is also of utmost importance in ESWL [13, 17]. Concerning the kidney midzone (hilar) drainage, our results show that this region is drained by paired calyces arranged in two rows (anterior and posterior) in 95.7% of the endocasts (Figure 6.26), which is of relevance to endourologists accessing and treating the mid kidney.

Anatomic relationship of intrarenal vessels (arteries and veins) with the kidney collecting system: importance for puncture intrarenal access

Percutaneous nephrostomy is the procedure of choice for temporary drainage of urine and for gaining access to the kidney during numerous endourologic and interventional procedures. The development of new percutaneous techniques, as well as a variety of instruments, has enabled the replacement of several open surgeries by percutaneous therapy (renal abscess, calyceal diverticulum, infundibular stenosis, ureteropelvic junction obstruction (UPJO), some cases of upper tract urothelial tumors, and even nephrectomy) [18–20]. Percutaneous procedures are relatively invasive and complications may occur. One of the most significant complications is vascular injury that occurs when the urologist is obtaining intrarenal access. This problem may have several consequences, including intraoperative hemorrhage, hypotension, loss of functioning renal parenchyma, arteriovenous fistula, and pseudoaneurysm [21–25].

The goal of this section is to offer a detailed anatomic depiction of the intrarenal vessels and their relationships to the collecting system, and show how to perform safe percutaneous intrarenal access by keeping as many renal vessels as possible intact during puncture.

We analyzed 62 retrograde pyelograms and their corresponding 3D polyester resin corrosion endocasts of the kidney collecting system, together with the intrarenal arteries and veins, obtained from fresh cadavers.

The kidneys were punctured under fluoroscopic guidance and the endocasts obtained with needles positioned at the site of puncture (Figure 6.27). For comparative analysis, we studied kidneys that had been punctured through a calyceal infundibulum and kidneys punctured through a calyceal fornix.

Intrarenal access through an infundibulum

Figure 6.13 shows the basic anatomy of the renal collecting system. Keeping those anatomic landmarks in mind, note that a puncture through an infundibulum (in any region of the kidney) presents clear hazards [26].

Superior pole

Puncture is most dangerous through the upper pole infundibulum because this region is surrounded almost completely by large vessels (Figure 6.28). Infundibular

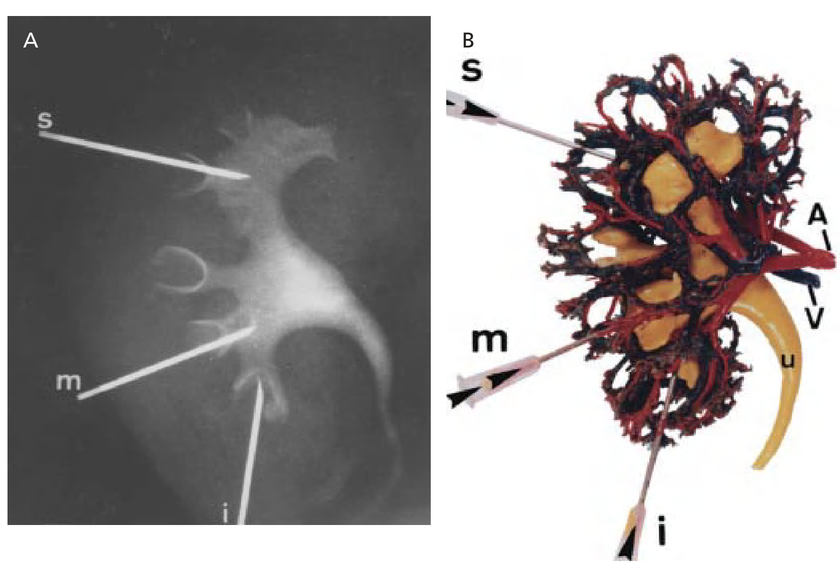

Figure 6.27 (A) Anterior view of a retrograde pyelogram from a right kidney showing the superior pole (s), mid kidney (m), and inferior pole (i) punctures. These punctures were performed after polyester resin injections into the arterial and venous systems, while the resins were still in the gel state. Note that the injected resins are not opaque to X-rays. (B) Posterior view of the corresponding corrosion endocast obtained after contrast removal and pelviocalyceal system injection with resin. The needles are maintained in their original places. s, superior pole puncture; m, mid kidney puncture; i, inferior pole puncture. The arrowheads show the tracts of the needles. A, renal artery; V, renal vein; u, ureter (reproduced from Sampaio *et al*. [24], with permission).

arteries and veins course parallel to the anterior and posterior aspects of the upper pole infundibulum. In our series, injury to an interlobar (infundibular) vessel was a common consequence of puncturing the upper pole infundibulum (67% of kidneys) (Figure 6.29); the injured vessel was an artery in 26% of those cases.

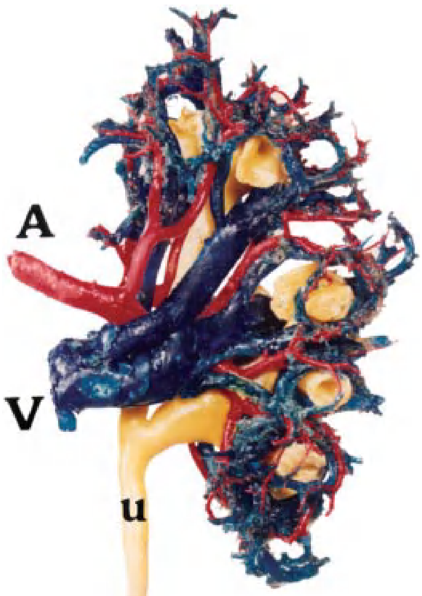

Figure 6.28 Oblique medial view of an endocast of arterial (A), venous (V), and pelviocalyceal systems from a left kidney. This shows the upper infundibulum almost completely encircled by infundibular arteries and veins. This anatomic arrangement makes upper pole infundibular puncture especially dangerous. A, renal artery; V, renal vein; u, ureter (reproduced from Sampaio *et al.* [24], with permission).

The most serious vascular accident in upper infundibulum puncture is lesion of the posterior segmental artery (retropelvic artery). This event may occur because this artery was crossed by and is related to the posterior surface of the upper infundibulum in 57% of the endocasts (Figure 6.30) [27]. Figure 6.31 shows an upper infundibulum puncture in which the needle tract produced complete laceration of the posterior segmental artery. Because the posterior segmental artery (retropelvic artery) may supply up to 50% of the renal parenchyma, injury to it may result in significant loss of functioning renal tissue, as well as causing hemorrhage [28].

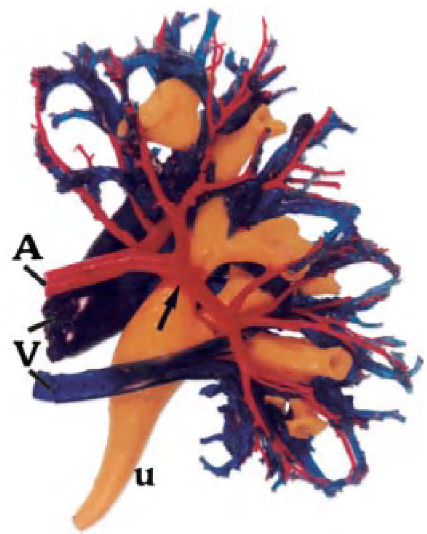

Figure 6.30 Posterior view of an endocast from a right kidney. This shows the posterior segmental artery (retropelvic artery) crossing the posterior surface of the upper infundibulum (arrow). A, renal artery; V, renal vein; u, ureter (reproduced from Sampaio *et al.* [24], with permission).

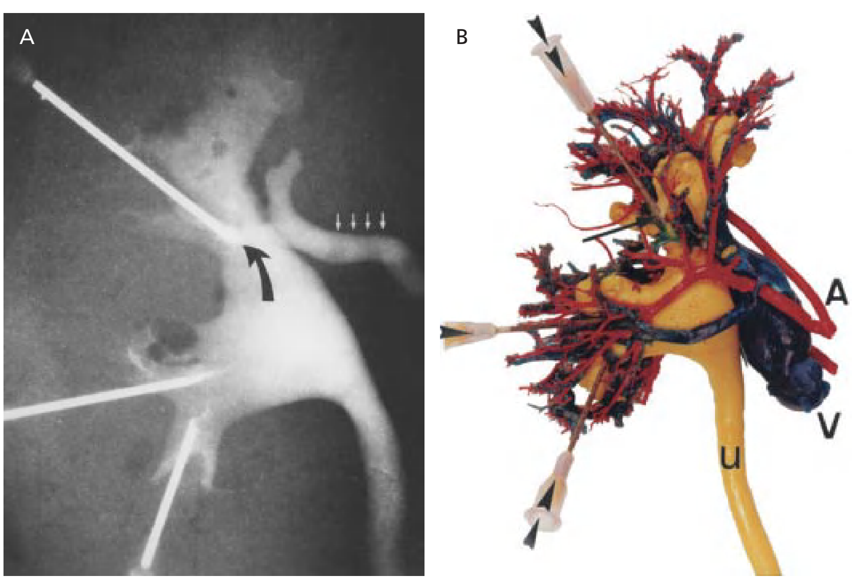

Figure 6.29 (A) Posterior view of a retrograde pyelogram from a left kidney. Puncture performed through the upper infundibulum has injured an infundibular vein (curved arrow). Note the contrast in the retropelvic vein (short arrows). (B) Posterior view of the corresponding endocast reveals the site of the lesion (arrow). Arrowheads show the needle tracts. A, renal artery; V, renal vein; u, ureter (reproduced from Sampaio *et al.* [24], with permission).

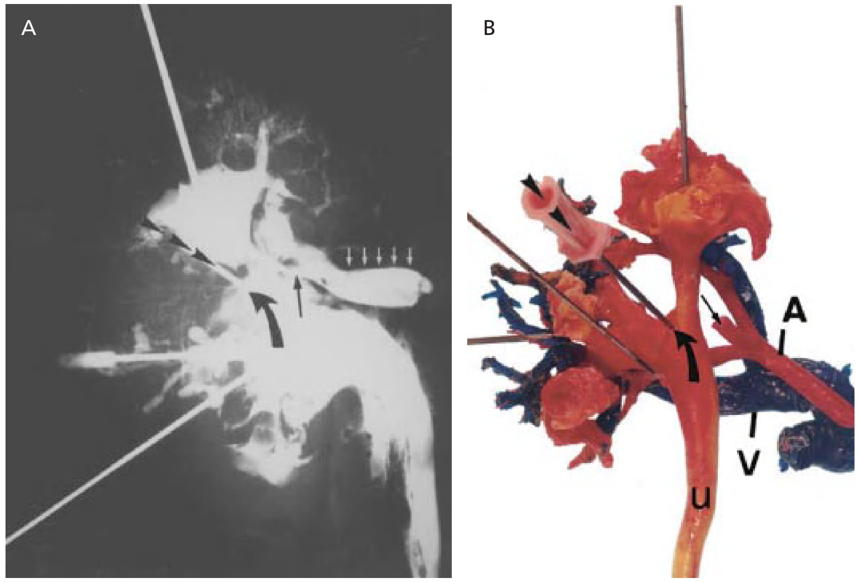

Figure 6.31 (A) Posterior view of a retrograde pyelogram from a left kidney. This shows contrast extravasation, and contrast in the arterial system and main trunk of the renal artery (short arrows). The retropelvic artery was injured by the needle (needle tracts shown by the arrowheads). The curved arrow points to the site of the lesion; the long arrow points to the retropelvic artery filled with contrast extravasated from the collecting system. (B) Posterior view of the corresponding endocast. This shows the divided retropelvic artery (arrow) and the needle (arrowheads) responsible for the lesion (curved arrow). A, renal artery; V, renal vein; u, ureter (reproduced from Sampaio *et al.* [24], with permission).

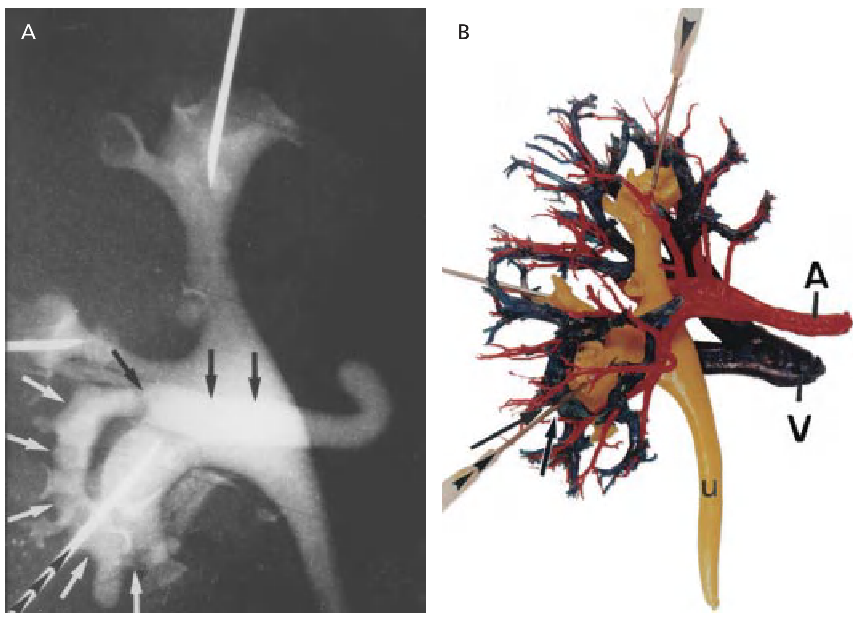

Figure 6.32 (A) Posterior view of a retrograde pyelogram from a left kidney. This shows a puncture performed through the inferior infundibulum. A venous lesion and the contrast in a large venous arcade draining to the retropelvic vein (arrows) can be seen. The arrowheads show the tract of the needle.
(B) Posterior view of the corresponding endocast reveals the site of the lesion in the venous arcade (arrows). The arrowheads show the tracts of the needles. A, renal artery; V, renal vein; u, ureter (reproduced from Sampaio *et al*. [24], with permission).

Middle kidney

Intrarenal access through the mid kidney infundibulum caused arterial lesion in 23% of the kidneys studied. The middle branch of the posterior segmental artery was injured more often than any other vessel.

Inferior pole

The posterior aspect of the lower pole infundibulum is widely presumed by endourologists and interventional radiologists to be free of arteries. It is considered, therefore, to be a safe region through which to gain access to the collecting system and to place a nephrostomy tube. In about 38% of the kidneys examined, however, an infundibular artery was found in this region [27]. Thus, significant complications may develop as a consequence of a posterior approach through the supposedly vessel-free lower infundibulum [22, 25, 26]. We found an arterial injury in 13% of kidneys we had punctured through the lower pole infundibulum.

Concerning the veins, we found large venous anastomoses, similar to collars, around the calyceal infundibula (the so-called calyceal necks) in many of the kidneys we studied [7]. Puncture through the lower pole infundibulum therefore also risks injury to a venous arcade (Figure 6.32). A venous lesion usually heals spontaneously, but consequent hemorrhage may be problematic during the procedure.

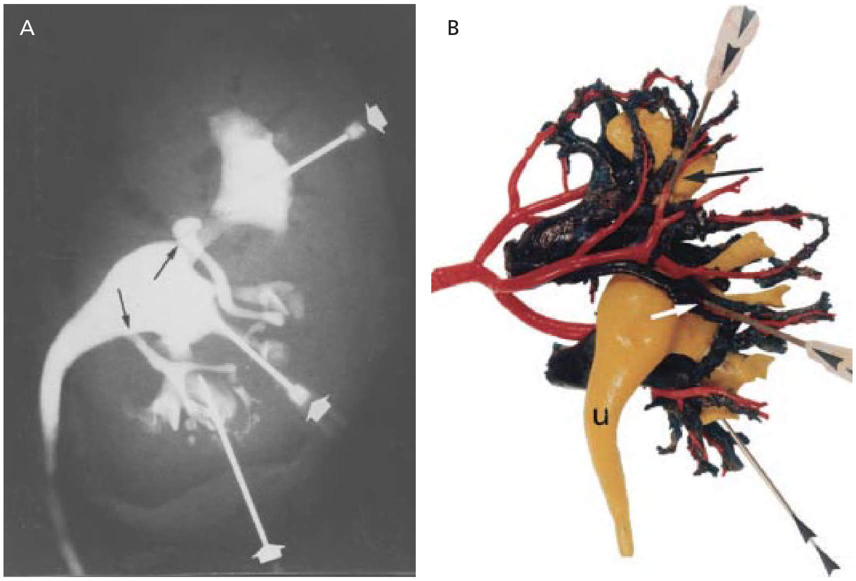

Figure 6.33 (A) Posterior view of a retrograde pyelogram from a right kidney reveals superior, middle, and inferior punctures (arrowheads) and contrast in the superior and inferior infundibular arteries (arrows).
(B) Posterior view of the corresponding endocast reveals injury to an upper infundibular artery (black arrow). The mid kidney puncture (white arrow) was a through-and-through (two walls) puncture and injured an anterior segmental artery. The injured vessel furnished the posteroinferior branch filled with contrast on the pyelogram. The arrowheads show the tracts of the needles. U, ureter (reproduced from Sampaio *et al*. [24], with permission).

Our findings clearly demonstrate that percutaneous nephrostomy through an infundibulum of a calyx is not a safe route, because this type of access poses an important risk of significant bleeding from interlobar (infundibular) vessels.

Infundibular puncture also creates the hazard of through-and-through (two-wall) puncture of the collecting system (Figure 6.33). Because major segmental branches of the renal artery, as well as major tributaries of the renal vein, are positioned on the anterior surface of the renal pelvis, marked hemorrhage may occur as a result of an anterior through-and-through perforation. In addition, effective tamponade of injured anterior vessels is difficult because they lie distantly in the nephrostomy tract [24, 26, 29].

Although infundibular access is feasible in some circumstances and must be considered in specific situations (e.g. some difficult anatomic cases), the surgeon must evaluate the risk of an arterial lesion, primarily in the superior pole and in the mid kidney [24].

Intrarenal access through the renal pelvis

Direct puncture of the renal pelvis for endourologic surgery should never be performed. Besides the fact that the nephrostomy tube inserted at this site is easily dislodged and difficult to reintroduce during the operative maneuvers, renal pelvis puncture has a prohibitive and unnecessary risk of injuring a retropelvic vessel (artery and/or vein) [7, 22, 27].

Intrarenal access through a calyceal fornix

When we made a puncture through a fornix of a calyx, venous injury occurred in fewer than 8% of the kidneys. These injuries occurred indiscriminately in the upper pole, mid pole, and lower pole calyces. We did not detect any arterial lesions as a consequence of a forniceal puncture [24].

Where to puncture for intrarenal access

In conclusion, the high rate of vascular injury and the possibility of associated complications mean that *a nephrostomy tube should not be placed through an infundibulum of a calyx* (Figure 6.34). On the other hand, and regardless of the region of the kidney, *puncture and placement of a nephrostomy tube through a fornix of a calyx is safe* and should be the site chosen by the operator (Figure 6.35). Even in the superior pole, intrarenal puncture through a calyceal fornix is harmless (Figure 6.36). In addition, when puncturing through a fornix of a calyx, in case of lesion, injury is always to a peripheric vessel, such as a small venous arcade (Figure 6.37).

Vascular anatomy and intrarenal endourologic surgery

The development of new endourologic procedures and techniques, as well as special operative instruments, allowed an important improvement in endourologic intrarenal surgery to treat numerous renal diseases and/or help with the management of difficult cases in endourology [19, 20, 29, 30].

A serious and troublesome complication of endoscopic intrarenal operation is bleeding from an injured vessel [29, 30]. To avoid such injury, the position of the intrarenal vascular structures must be known in relation to the collecting system. That knowledge must consider

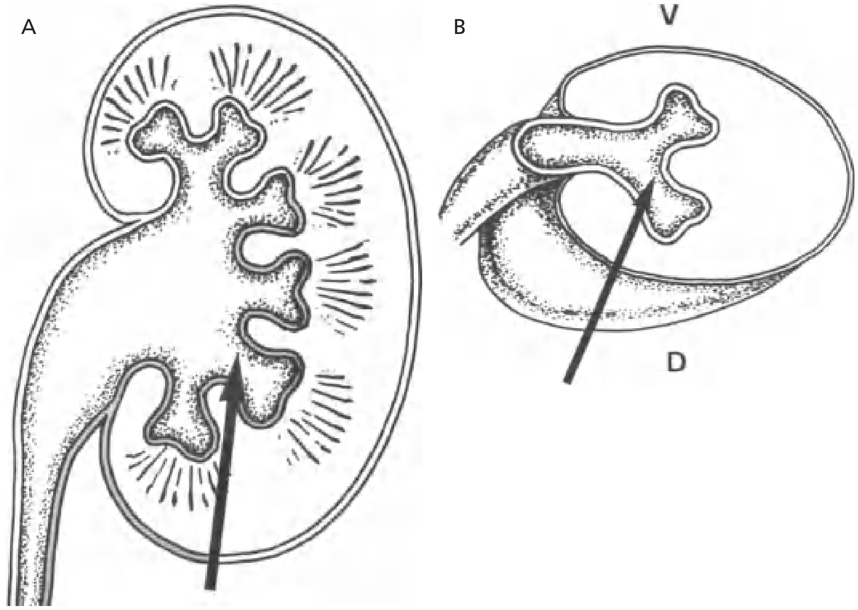

Figure 6.34 (A) Schematic of a posterior view of a longitudinal section of a right kidney showing an intrarenal puncture performed through a calyceal infundibulum (arrow). This type of puncture should *not* be performed because it carries a high risk of vascular injury. (B) Schematic of a superior view of a transverse section of a kidney also shows an intrarenal puncture through a calyceal infundibulum (arrow); again this is *not* a recommended route. V, ventral region; D, dorsal region.

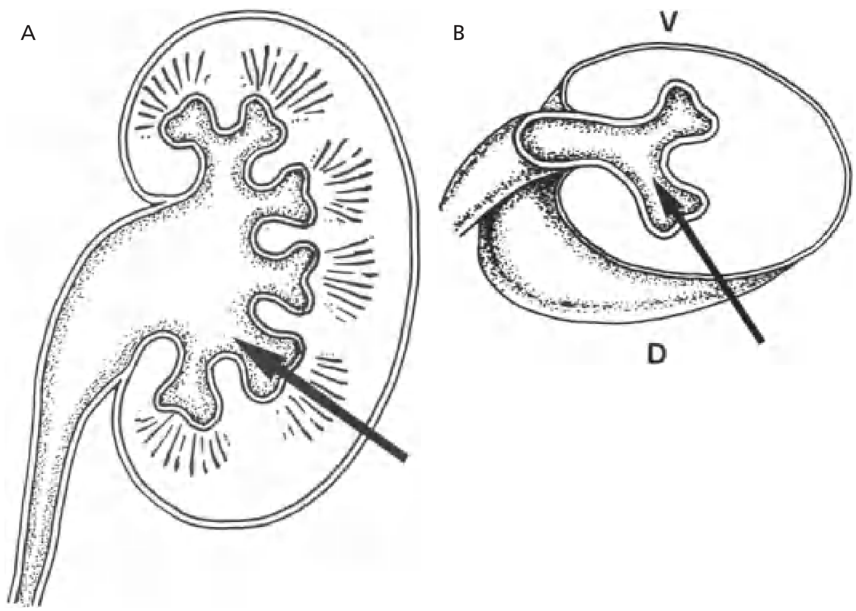

Figure 6.35 (A) Schematic of a posterior view of a longitudinal section of a right kidney showing an intrarenal puncture performed through a calyceal fornix (arrow). This type of puncture is safe and is associated with a very low incidence of vascular injury. (B) Schematic of a superior view of a transverse section of the kidney shows an intrarenal puncture through a calyceal fornix (arrow), a route that is strongly recommended. V, ventral region; D, dorsal region.

each specific kidney region with emphasis on the infundibular regions [6, 31].

We analyzed 82, 3D polyester resin corrosion endocasts of the kidney collecting system together with the intrarenal arteries, and 52 endocasts of the kidney collecting system together with the intrarenal veins, obtained according to the injection–corrosion technique described previously [7, 11, 27].

Regional vascular anatomy of the kidney

Superior pole

The upper infundibulum was almost completely surrounded by segmental or interlobar (infundibular) arteries in 86.6% of the endocasts (Figure 6.38). In 84.6% of the endocasts, an anterior and a posterior venous plexus were in close relationship to the upper infundibulum (Figure 6.39).

Figure 6.36 Superior view of an endocast from a left kidney shows that, even in the superior pole, a puncture through the fornix of a calyx (arrow) is safe.

Figure 6.37 Posterior view of an endocast from a right kidney with an inferior puncture performed through a fornix of a calyx. The arrows point to a lesion in a small peripheric venous arcade. The arrowheads show the needle tract. P, renal pelvis; u, ureter.

Middle kidney

The anterior aspect of the mid kidney infundibulum of a major or a minor calyx was in close relationship to a segmental or an infundibular artery in 65% of the endocasts (Figure 6.38A). In the posterior aspect of all the endocasts, we found at least one mid kidney infundibulum in close relationship to the mid subdivision branch of the posterior segmental artery (retropelvic artery) (Figure 6.38B).

Concerning the veins, the anterior aspect of a middle infundibulum was in contact with an anterior tributary of the renal vein in 71% of the endocasts. The posterior aspect of a middle infundibulum was in close relationship to a posterior tributary of the renal vein in 21% of the endocasts (Figure 6.39).

The vascular relations to mid kidney infundibula are very variable because they follow the variations in the calyces, of which there are many in this region [8, 27].

Inferior pole

In all endocasts, the lower infundibular anterior aspect of a major or a minor calyx was in close relationship to a branch of the anteroinferior or inferior segmental artery (Figure 6.38A). Concerning the posterior aspect, in 38% of the endocasts, an extension of the posterior segmental artery itself was in close relationship to the lower major calyceal infundibulum. In the other 62%, the posterior aspect of the lower major calyceal infundibulum was free from arteries; nevertheless, the posterior aspect of the lowermost minor calyx infundibulum was related to an artery in all endocasts (Figure 6.38B).

With respect to veins, the anterior aspect of at least one lower infundibulum was in contact with an intrarenal vein in all endocasts. The posterior aspect of a lower infundibulum was in close relationship to a large tributary of the renal vein in 21% of the endocasts (Figure 6.39). In addition, in the inferior pole, a collar-like venous anastomosis around the minor calyces infundibula (calyceal necks) is often found (Figure 6.39).

Where to incise the kidney collecting system based on vascular anatomy

If any intrarenal operation is necessary to free entrapped stones, to treat strictures and diverticula, to incise a narrowed infundibulum, to correct other anomalies that can cause stone formation, and even to facilitate the

Figure 6.39 Posterior view of an endocast (pelviocalyceal system and veins) from a right kidney shows a large venous plexus in close relationship to the upper infundibulum (short arrow). The arrowhead points to the posterior aspect of the lower infundibulum in close relationship to a large vein. The arrows encircle the collar-like venous anastomosis around the neck of the lower minor calyx (reproduced from Sampaio [31], with permission).

access for the rigid nephroscope to a specific calyx [29, 30], the operator must visualize the arterial relationships found most frequently in the area to be incised. It was established that the area first must be examined under direct vision to be certain that there are no arterial pulsations [29], and then a short incision to a depth of 1–2 mm may be made. If necessary, e.g. the infundibulum remains thick, it is better to make a second incision in a different site than to deepen the first incision, due to the risk of injuring a large vessel [29, 31].

Even taking into account these technical recommendations, significant bleeding may occur during intrarenal endourologic surgery [29, 30]. Also, arterial pulsations are not always readily identifiable endoscopically during surgery, mainly because patients may be hypotensive due to anesthesia [6, 31].

Although it is difficult to eliminate bleeding completely, maintenance of anatomic orientation during all steps of the procedure and a thorough knowledge concerning the relationship between the pelviocalyceal system and the vessels are imperative to reduce vascular complications, improving the performance and safety of operations.

On the basis of the anatomic vascular background presented here, and considering that the circumference of an infundibulum is composed of four quadrants, we

Publisher's Note:

Figure 6.40 Schematics of the renal collecting system. (A) Anterior view of a right kidney pelviocalyceal system shows the sites to be incised in infundibular stenosis; s, superior quadrant; i inferior quadrant. (B) Transverse section through an infundibulum shows the four quadrants that comprise the infundibular circumference and the two preferred areas to be incised (s, superior quadrant; i, inferior quadrant). This also shows the anterior (a) and posterior (p) quadrants, which are usually closely related to vessels (reproduced from Sampaio [31], with permission).

advise that the infundibular incision is made in the superior or inferior quadrant (Figure 6.40), because in general this area is not in relation to large vascular structures. In contrast, the posterior and, especially, the anterior aspects of infundibular surfaces are frequently related to intralobar (infundibular) vessels (Figure 6.40). *Anterior incisions must always be avoided.* From an anatomic standpoint, if more than one infundibular incision is necessary, we recommend the following sequence:

- First incision in the superior quadrant;
- Second incision in the inferior quadrant;
- Third incision between the superior and posterior quadrant;
- Fourth incision between the inferior and the posterior quadrant;
- Fifth incision in the posterior quadrant.

Because the free circulation throughout the venous system prevents parenchyma loss and ischemia, arteries are considered of utmost importance in intrarenal endosurgery. Nevertheless, veins should be considered as well, because an injury to a large vein would result in important and troublesome back bleeding. Moreover, as the veins do not pulsate, they cannot be perceived through the nephroscope; therefore, only knowledge of the anatomic relationships between the veins and the collecting system will avoid venous lesion. If it is necessary to make an incision in the infundibulum (neck) of a minor calyx, especially in the lower calyces, the operator should remember that the regions close to the calyceal cups may be surrounded by venous collars (Figure 6.39). In these cases, it is better to perform short radial incisions (up to 1 mm in depth) in the quadrants described previously, in order to avoid venous collar lesions.

Vascular anatomy of the ureteropelvic junction: importance for endopyelotomy

Since its clinical introduction, the endoscopic treatment of UPJO, endopyelotomy, has almost completely replaced open pyeloplasty for this procedure [32–37]. It has a comparable success rate to open surgery and is applicable to congenital and acquired conditions [35–38]. Today, endopyelotomy is a common procedure for both primary and secondary UPJO [39]. In spite of the recently high success rate of laparoscopic pyeloplasty, endopyelotomy continues to be more commonly performed in academic centers [40].

Because endopyelotomy is based on an intubated pyeloplasty (ureteropelvic incision followed by stenting for 1–6 weeks) [32, 35–38, 41], to be successful the endoscopist must incise the full thickness of the muscle at the stenotic wall of the UPJ until periureteral fat becomes visible. This deep incision must be carried out whether the approach is through a nephrostomy tract, by ureteroscopy, or with an Acucise catheter, and whether the instrument used to incise the stricture is a cold knife or an electrosurgical probe [42].

Incising the UPJ until the perirenal space is entered obviously carries the risk of injuring a retroperitoneal vessel [43–45]. In fact, the most significant complication

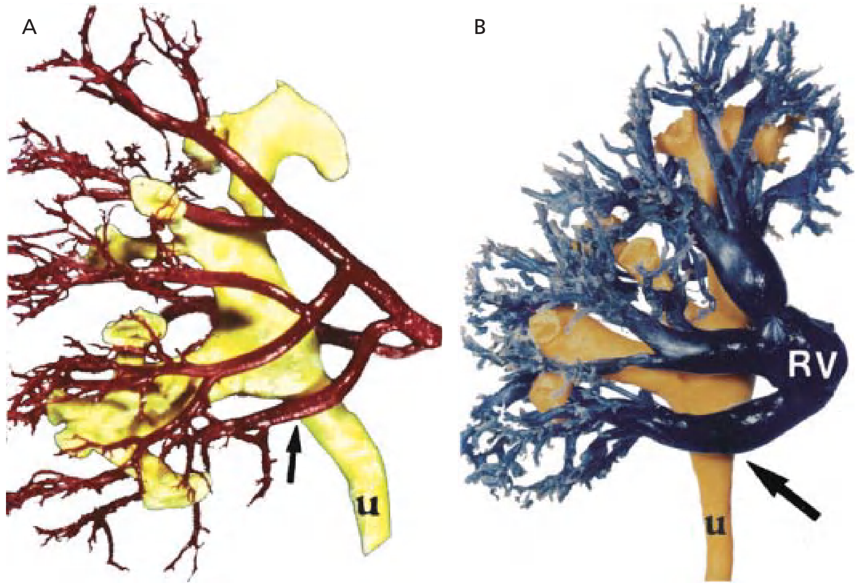

Figure 6.41 (A) Anterior view of a right kidney endocast (pelviocalyceal system together with the intrarenal arteries) shows a close relationship between the inferior segmental artery and the anterior surface of the ureteropelvic junction (UPJ; arrow). u, ureter. (B) Anterior view of a right kidney endocast (pelviocalyceal system together with the intrarenal veins) shows a close relationship between a vein draining the lower pole and the UPJ (arrow). RV, renal vein; u, ureter (reproduced from Sampaio and Favorito [44], with permission).

Publisher's Note:

Figure 6.42 Anterior view of a right kidney endocast (pelviocalyceal system together with the intrarenal arteries and veins) shows the anterior surface of the ureteropelvic junction in close relationship with the inferior segmental artery (arrowhead) and a tributary of the renal vein (arrow). A, renal artery; V, renal vein; u, ureter (reproduced from Sampaio [59], with permission).

of this procedure is vascular injury, followed by severe hemorrhage and/or formation of an arteriovenous fistula [33, 34, 36, 46–50]. To protect the arteries from lesion, it has been recommended to examine via intrarenal endoscopy the area to be incised for any arterial pulsation and, if detected, to avoid incising that site. Nevertheless, arterial pulsations are not always readily identifiable endoscopically during surgery, mainly because patients may be hypotensive due to anesthesia [31]. In addition, because veins do not pulsate, endoscopic examination of the area to be incised will not prevent a venous lesion [7, 31].

The risk of injuring a large vessel during endopyelotomy can be greatly reduced or even eliminated if the endourologist understands and keeps in mind the 3D vascular relationships to the UPJ [44, 45, 51]. This section describes the vascular anatomy of the UPJ and this should be used to perform endopyelotomy safely and efficiently.

We analyzed 146 3D polyester resin corrosion endocasts of the pelviocalyceal system together with the intrarenal arteries and veins [45].

Anterior vascular ureteropelvic junction relationships

In 65% of the endocasts there was a prominent artery, vein, or both vessels in close relationship with the ventral surface of the UPJ (Figures 6.41 and 6.42). Among these endocasts, the relationship was with the inferior segmental artery in 45% (Figure 6.43).

Concerning patient selection for treatment of UPJO, it remains controversial whether or not it is important to diagnose anterior crossing vessels. Van Cangh *et al.* obtained preoperative digital angiography in patients prior to endopyelotomy and found an associated vessel in 39% of those with UPJO [52]. These authors stated that the presence of an anterior crossing vessel with either mild or severe hydronephrosis resulted in a success rate of only 50% and 39%, respectively. More recently, Van Cangh *et al.* stated that significant risk factors for endopyelotomy failure are crossing vessels, degree of hydronephrosis, length of stricture, and renal function [53]. Rehman *et al.* emphasized the importance of spiral CT angiography for delineating the renal vascular anatomy before open retroperitoneal UPJO repair

[54]. They described two patients with repair failure of UPJO in whom anterior vessels were missed during open retroperitoneal surgery. Laparoscopic transperitoneal secondary dismembered pyeloplasty with posterior displacement of the crossing vessel was successfully performed in each case.

On the other hand, Smith stated that this kind of study would be justified only if there were evidence that such vessels were etiologic in UPJ obstruction or if there were a risk of incising the vessel during endopyelotomy [37]. More recently, Gupta and Smith stated that the current data suggest that the finding of crossing vessels preoperatively need not significantly influence the treatment given [55]. Corroborating this view, Nakada *et al*. reported that helical CT detected significant anterior or posterior crossing vessels in 38% of patients following successful endopyelotomy [56]. In their opinion, the adverse influence of the crossing vessel is not sufficient to justify the added expense of preoperative angiography, spiral CT, or endoluminal ultrasound. Also, documenting the presence of a crossing vessel is inadequate to confirm that the vessel is causing obstruction. None of the current UPJ imaging techniques can distinguish crossing arteries that are the direct cause of obstruction from those that are not [57, 58]. Therefore, in the absence of a prospective randomized trial comparing the results of open pyeloplasty and endopyelotomy, including the investigation of crossing vessels, the imaging of these crossing vessels before surgery is controversial.

It is worth pointing out that in Van Cangh *et al.*'s series, 39% of the patients had a crossing vessel anteriorly to the UPJ, and these were considered to be anomalous arteries [52]. This consideration disagrees with our extensive vascular anatomic studies [43–45, 59]. Of 280 endocasts of the pelviocalyceal system together with the intrarenal arteries and veins, we found a close relationship between a normal artery, vein, or both and the anterior surface of the UPJ in 65.1% (Figures 6.41–6.43) [45, 59]. In 45.2% of the endocasts there was a close relationship between the inferior segmental artery and the anterior surface of the UPJ when this vessel passed in front of this region to enter the inferior pole (Figure 6.43) [45, 59]. This vessel is neither accessory nor aberrant, but, rather, a normal segmental artery that maintains a consistent anatomic relationship with the anterior surface of the UPJ without compressing the junction [45, 59, 60]. The mere presence of crossing vessels in the UPJ does not mean that they are necessarily obstructive [37]. We consider that an anomalous artery crossing the UPJ and causing obstruction in 39% of patients, as described by Van Cangh *et al*. [52], is quite a high incidence. It is possible that many of the vessels seen close to the UPJ during angiography and described as anomalous were in fact normal segmental arteries. They may not cause the obstruction but rather increase the dilation of a redundant renal pelvis previously obstructed by a primary muscular defect at the UPJ. In such a situation, the dilated renal pelvis balloons over the anterior crossing vessel, and the resulting angulation appears to worsen the obstruction [45]. Therefore, the exact role of crossing vessels in obstruction and the success of endopyelotomy are yet to be determined [37, 55].

With respect to the presence of multiple renal arteries, we found an inferior polar artery crossing anteriorly to the UPJ in only 6.8% of 266 renal arterial pedicles analyzed (Figure 6.44) [61] Also, in only a few cases did this inferior polar artery pass close to the UPJ. Therefore, the

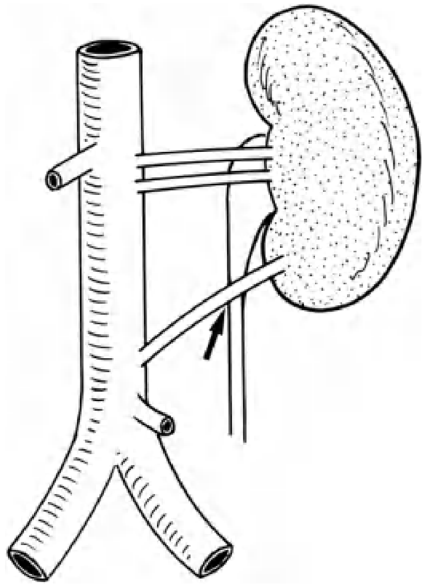

Figure 6.44 Schematic of an anterior view of a left kidney showing an inferior polar artery (arrow) crossing anterior to the ureteropelvic junction (incidence of 6.8%).

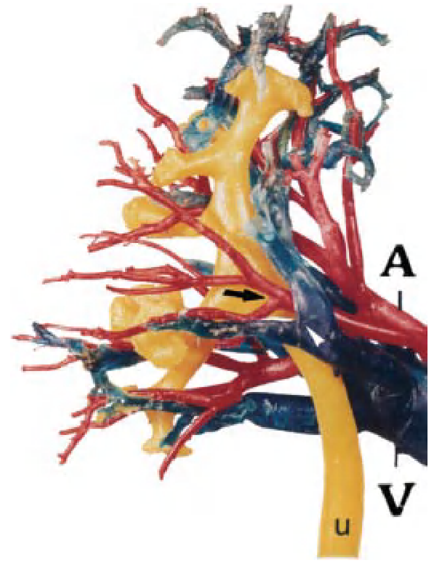

Figure 6.45 Posterior view of an endocast of a left kidney (pelviocalyceal system together with the intrarenal arteries and veins). A dorsal tributary of the renal vein (arrowhead) and the posterior segmental artery (retropelvic artery, arrow) are in close relationship to the posterior aspect of the ureteropelvic junction. A, renal artery; V, renal vein; u, ureter (reproduced from Sampaio and Favorito [44], with permission).

presence of an anomalous vessel crossing the UPJ and causing obstruction is uncommon.

For patients with a crossing vessel and minimal-to-moderate hydronephrosis, laparoscopic clipping and incision of the crossing artery has been reported [52]. We emphasize that this approach should not be used, because it results in loss of functioning renal parenchyma. It was well demonstrated and stressed that all renal arteries, even in cases of multiple arteries, are terminal vessels; therefore, clipping the vessel will cause renal infarction [28]. As we have shown previously, the artery supplying the inferior pole of the kidney (inferior segment) represents 7.4–38% of the total kidney area of functioning renal parenchyma (median area of the inferior segment, 22.6%) [28]. For that reason, if it is confirmed that the UPJO is caused by a crossing artery, open surgery or a laparoscopic pyeloplasty with transposition of the crossing vessel should be proposed rather than clipping it [59].

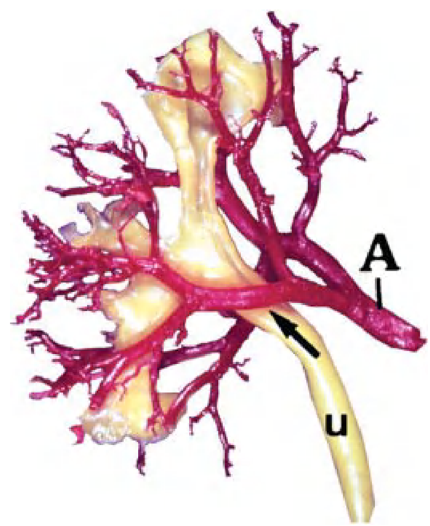

Figure 6.46 Posterior view of a left kidney endocast (pelviocalyceal system together with the intrarenal arteries and veins) shows the posterior segmental artery (retropelvic artery) in close relationship to the posterior aspect of the ureteropelvic junction (arrow). A, renal artery; u, ureter (reproduced from Sampaio and Favorito [44], with permission).

Posterior vascular ureteropelvic junction relationships

In 6.2% of the endocasts, we found a direct relationship between a large vessel (artery, vein, or both) and the dorsal surface of the UPJ (Figure 6.45). In all cases in which an artery crossed the dorsal surface of the UPJ (3.5%), the vessel was the posterior segmental artery, also known as the retropelvic artery (Figures 6.45 and 6.46).

Most authors recommend that the UPJ be incised alongside its posterolateral aspect, but our findings indicate that this poses a serious risk of injuring a retropelvic vessel. In fact, even when the procedure is performed by experienced endourologists, the incidence of severe hemorrhage when the UPJ is incised posterolaterally is 12% [36]. A posterior or posterolateral incision at the

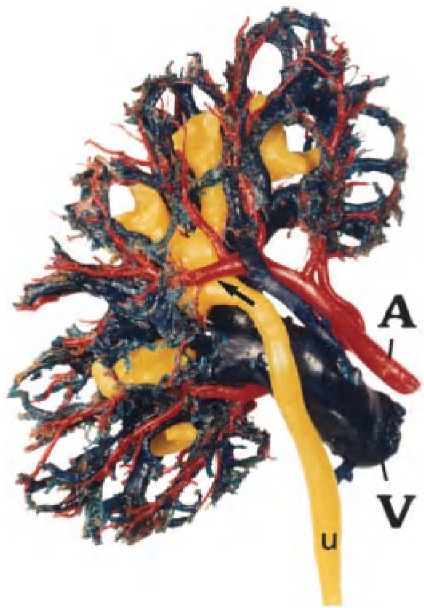

Figure 6.47 Posterior view of a left kidney endocast (pelviocalyceal system together with the intrarenal arteries and veins) shows the posterior segmental artery (retropelvic artery) crossing less than 1.5 cm (0.5 cm) above the posterior aspect of the ureteropelvic junction (arrow). A, renal artery; V, renal vein; u, ureter (reproduced from Sampaio and Favorito [44], with permission).

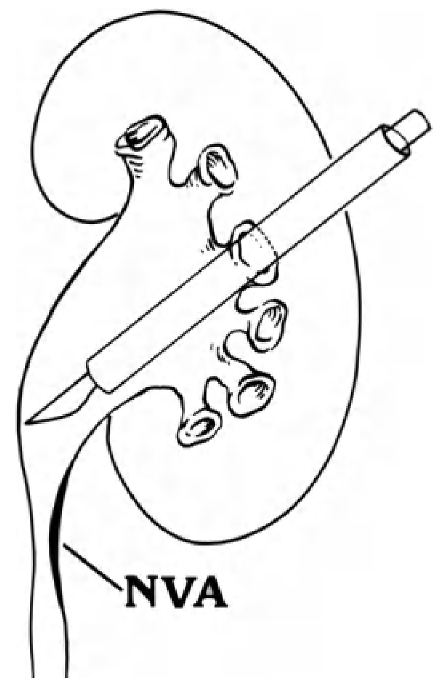

Figure 6.48 Schematic of an anterior view of a left kidney shows the area to be incised in endopyelotomy (arrow), the nonvascular area (NVA) of the ureteropelvic junction.

UPJ stenosis also presents the possibility of injury to the posterior segmental artery (retropelvic artery), which in addition to causing severe hemorrhage, can be associated with loss of a great portion of functioning renal tissue as a consequence of renal infarction. It is important to note that in some individuals, the posterior segmental artery supplies as much as 50% of the renal parenchyma [28].

In addition to the 6.2% of vessels that had a direct dorsal relationship with the UPJ by crossing it just at the posterior surface, another 20.5% of endocasts were characterized by a vessel crossing less than 1.5 cm above the dorsal surface of the UPJ (Figure 6.47). This is of great importance to surgeons who perform endopyelotomy, because to achieve a patent UPJ it is generally necessary to extend the endoscopic incision into the healthy tissue for 1–2 cm on each side (above and below) of the UPJ stenotic zone. This means that the risk of injury to a dorsal vessel is especially high in posterior and posterolateral incisions.

Furthermore, the risk of injury to a vessel that crosses less than 1.5 cm above the UPJ is particularly high in cases of extensive fibrosis and scarring tissue at the UPJ, because under such circumstances, it is necessary to make a long incision, sometimes extending into the renal parenchyma [45, 60]. Therefore, *posterior and posterolateral incisions at the UPJ must be avoided*.

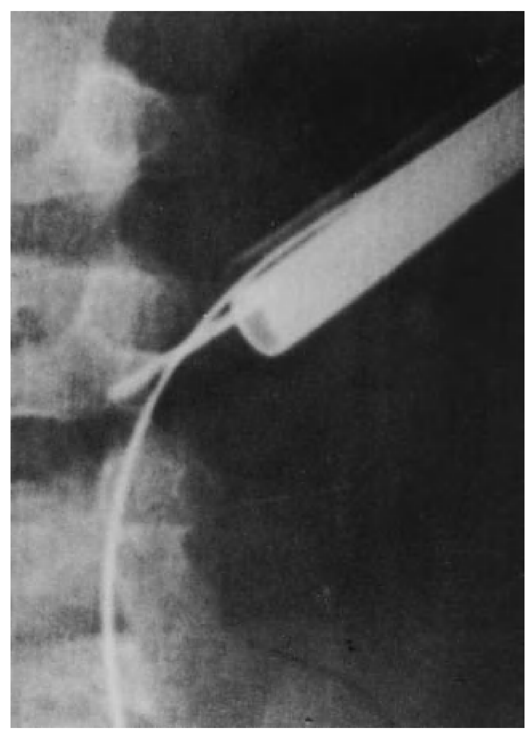

Figure 6.49 Cutting surface of a Sacks knife positioned laterally under fluoroscopic guidance during endopyelotomy.

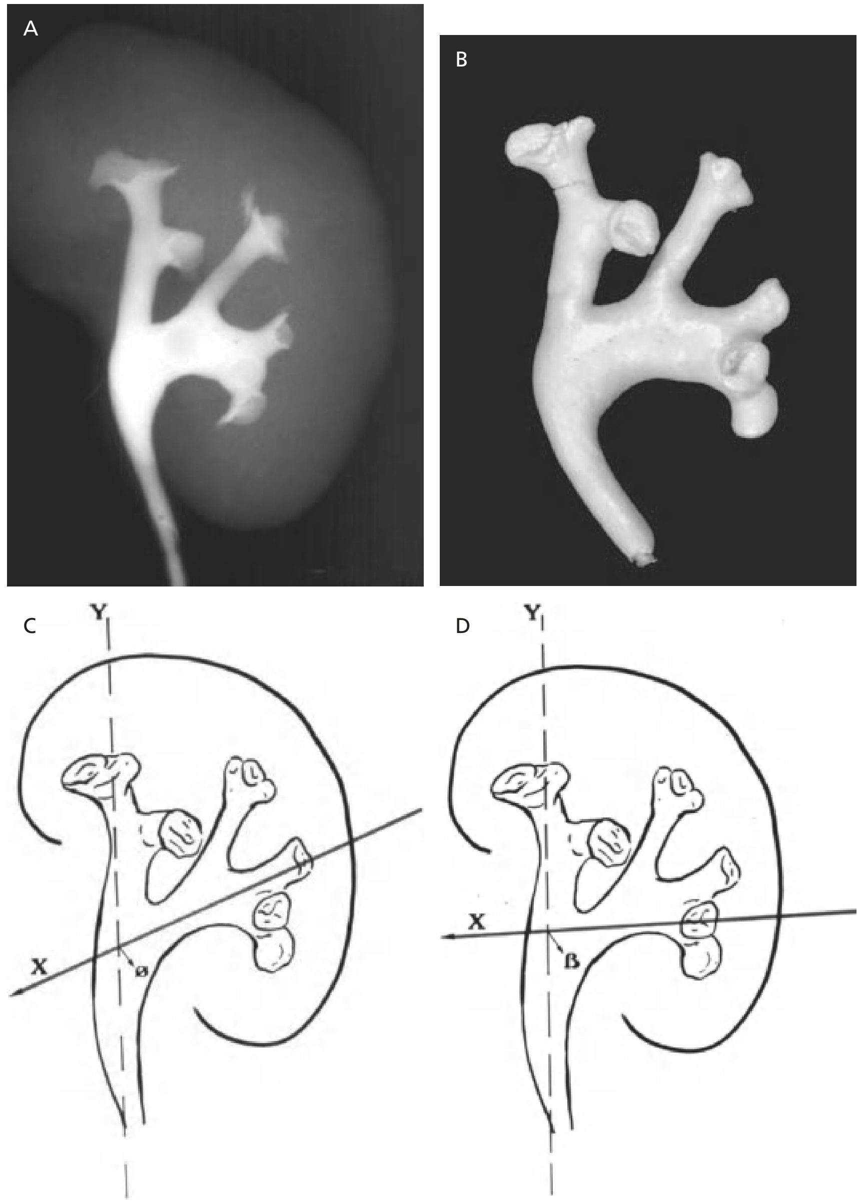

Figure 6.50 (A) Anterior view of a retrograde pyelogram of a left kidney. (B) Anterior view of a three-dimensional polyester resin corrosion endocast of the kidney in A. (C) Schematic of an anterior view of this pelviocalyceal system showing an access through an inferior pole calyx whose infundibulum forms an angle of greater than 90° (obtuse angle) with the ureteropelvic junction (UPJ). Y, first line drawn linking the central axis of the superior ureter with the central axis of the UPJ; X, second line drawn considering the central axis of the calyceal infundibulum chosen for intrarenal access. In this case, the angle formed (θ) measured 111°. This angle would allow easy frontal visualization of the UPJ. (D) Another inferior pole calyx in the same kidney forms a less obtuse angle (θ = 92°) but would still allow frontal visualization of the UPJ for percutaneous endopyelotomy.

Incision at the ureteropelvic junction stenosis based on the vascular anatomy

We recommend that the deep incision alongside the UPJ stenotic wall be performed *just laterally* (Figure 6.48). An incision at this site, which we have called the "nonvascular area" of the UPJ, avoids all important vessels that can be related anteriorly, posteriorly, or less than 1.5 cm above the posterior surface of the UPJ [44, 45, 60].

Even in cases of extensive scar tissue at the UPJ and in cases of vessels that were transposed posteriorly in an earlier dismembered pyeloplasty, the lateral incision in the "nonvascular area" of the UPJ is safe and avoids preoperative angiographic examinations. Also, an unsuspected polar inferior artery crossing anteriorly or posteriorly at the UPJ [47, 61] will be protected from injury.

Maintaining complete anatomic orientation under endoscopic vision is sometimes difficult. Consequently, it is our practice and recommendation to position the cutting instrument laterally and under fluoroscopic guidance (Figure 6.49) before starting the incision at the UPJ. Such a maneuver assures the surgeon that the incision will be made precisely in the lateral aspect, "the nonvascular area" of the UPJ [49, 60, 62].

Intrarenal anatomy for percutaneous access to the ureteropelvic junction

For percutaneous endopyelotomy, a puncture through an upper pole or a midzone calyx is usually recommended to establish a nephrostomy tract and to visualize directly the UPJ to be incised [36, 63, 64]. Although

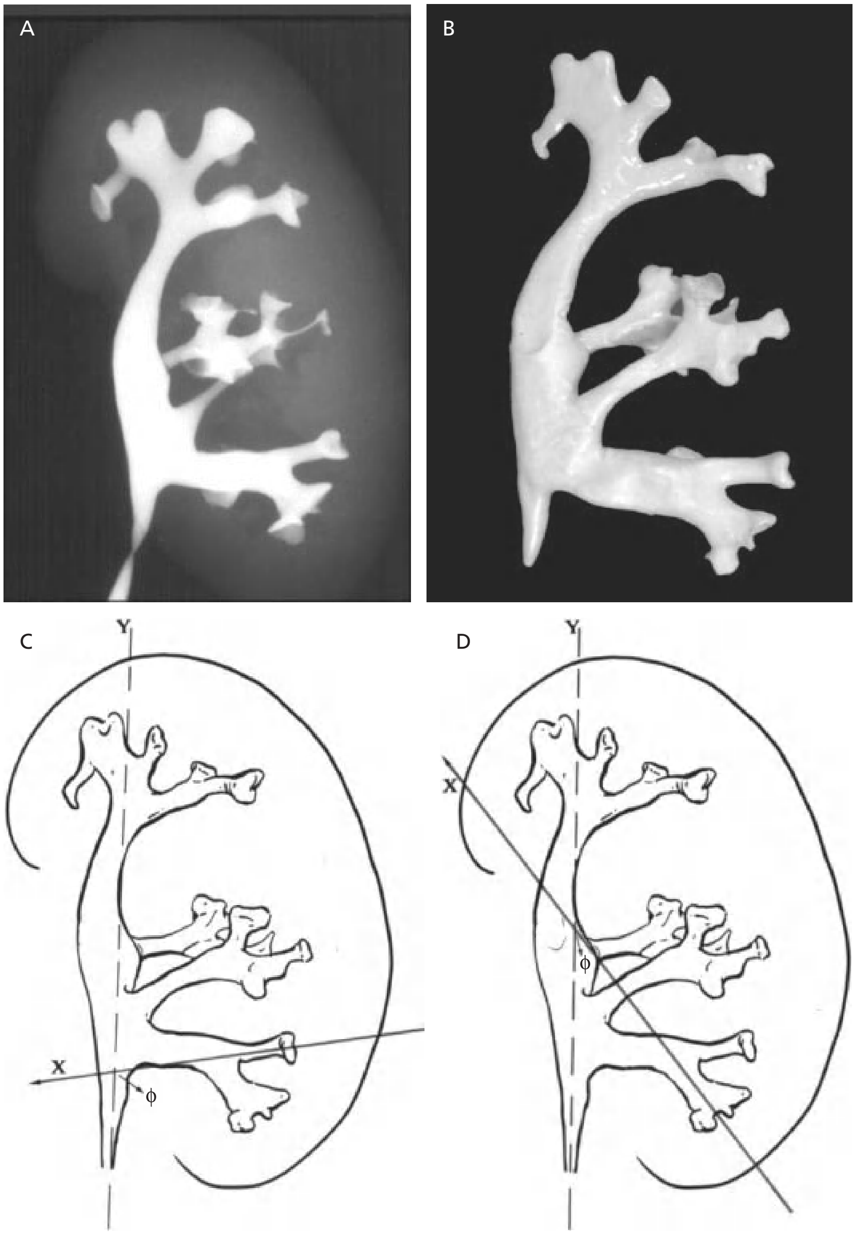

Figure 6.51 (A) Anterior view of a retrograde pyelogram of a left kidney. (B) Anterior view of a three-dimensional polyester resin corrosion endocast of the kidney in A. (C) Schematic of an anterior view of this pelviocalyceal system showing an access through an inferior pole calyx whose infundibulum forms an angle of greater than 90° (obtuse angle) with the ureteropelvic junction (UPJ). Y, first line drawn linking the central axis of the superior ureter with the central axis of the UPJ; X, second line drawn considering the central axis of the calyceal infundibulum chosen for intrarenal access. In this case, the angle formed (θ) measured 98°. This angle would allow easy frontal visualization of the UPJ. (D) Another inferior pole calyx in the same kidney forms an acute angle (θ = 38°) and would not allow frontal visualization of the UPJ for percutaneous endopyelotomy.

a supracostal approach provides an excellent access to the UPJ, this is at the cost of an increased risk of perforation of pleural and adjacent organs [4]. In our experience and based on the collecting system anatomy, *in patients without previous renal surgery*, we found that an upper pole puncture is rarely necessary. Also, a midzone puncture is necessary in only one-third of cases. In most patients, an access through a lower pole calyx enables a frontal visualization of the UPJ [65]. *The calyx should be selected based on the angle that is formed between the calyceal infundibulum and the UPJ.*

How to determine the angle

For evaluation of the angle, two lines must be drawn. The first line (y-axis) must link the central axis of the superior ureter to the central axis of the UPJ. The second line (x-axis) is the central axis of the calyx being considered for puncture (Figures 6.50–6.52).

The angle formed by the intersection of the lines is measured with a protractor (Figures 6.50–6.52). In clinical practice, however, we have found that it can be simply deduced whether the angle is larger or

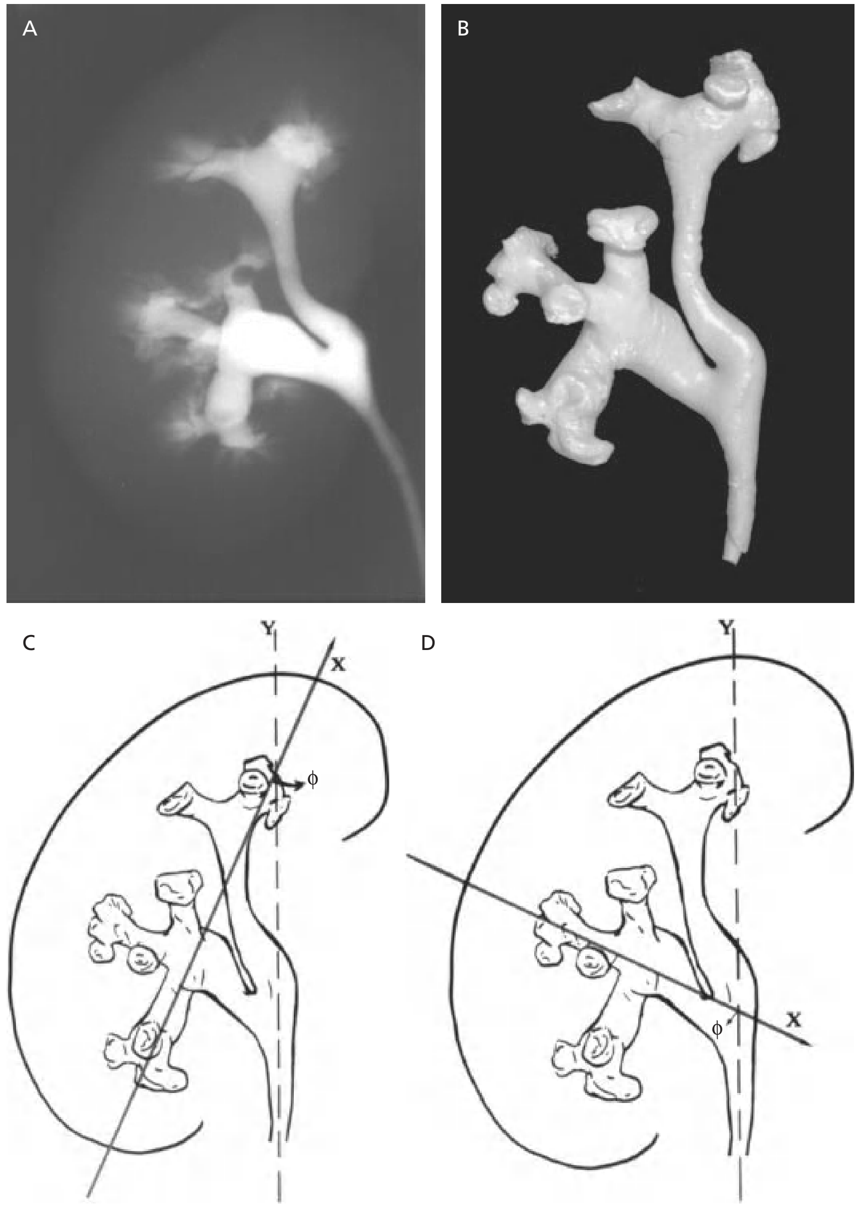

Figure 6.52 (A) Anterior view of a retrograde pyelogram of a right kidney. (B) Anterior view of a three-dimensional polyester resin corrosion endocast of the kidney in A. (C) Schematic of an anterior view of this pelviocalyceal system showing an access through an inferior pole calyx whose infundibulum forms an angle of greater than 90° (obtuse angle) with the ureteropelvic junction (UPJ). Y, first line drawn linking the central axis of the superior ureter with the central axis of the UPJ; X, second line drawn considering the central axis of the calyceal infundibulum chosen for intrarenal access. In this case, the angle formed (θ) measured 24°. This angle would probably render a frontal visualization of the UPJ impossible for performing percutaneous endopyelotomy. (D) Access though a midzone calyx whose infundibulum forms an obtuse angle (θ = 116°) and would allow easy frontal visualization of the UPJ for percutaneous endopyelotomy, without requiring a superior pole puncture.

smaller than 90° by examining the intersection of the lines.

How to select a calyx for puncture

An appropriate calyx can be chosen based on the angle that is formed between the calyceal infundibulum and the UPJ. If the chosen calyx forms an angle equal to or greater than 90° to the UPJ, the intrarenal access through this calyx will permit an easy and frontal visualization of the UPJ (Figure 6.53). Our anatomic studies showed that in around 70% of the cases, it is possible to find at least one posterior lower calyx whose infundibulum forms an angle greater than 90° to the UPJ.

The angle formed between the UPJ and the calyceal infundibulum must be determined for the chosen calyx, because the angle will vary for different calyces in the same region of the kidney, greater than 90° in some (98°in Figure 6.51C), and smaller than 90° in others (38° in Figure 6.51D). Therefore, by selecting an appropriate calyx based on analysis of the angle, it is possible to access the UPJ through a lower calyx in most cases.

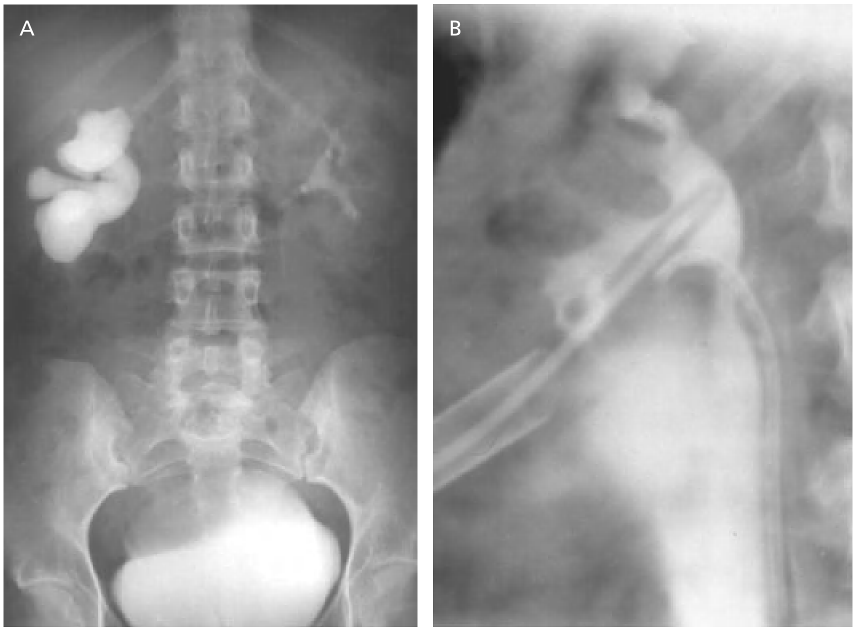

Figure 6.53 (A) Intravenous pyelogram from a 30-year-old woman shows a ureteropelvic junction (UPJ) obstruction with a dilated pelviocalyceal system. (B) Pyelogram performed through the nephrostomy tube immediately after endopyelotomy reveals contrast extravasation through the incision in the UPJ. The Amplatz sheath is being withdrawn. The endopyelotomy was easily performed through an inferior pole calyx.

In some cases (around 30%), it is necessary to puncture a midzone calyx, because in these cases all lower calyceal infundibula form angles smaller than 90° with the UPJ (Figure 6.52). We found at least one midzone calyx forming an angle equal to or greater than 90° with the UPJ in 208 pelviocalyceal systems [65].

In cases with a history of previous open surgery, or even percutaneous surgery, access through a midzone calyx must be considered, because there is a high possibility of perinephric scarring. Depending on the pelviocalyceal anatomy, a middle calyx puncture will offer easier access to the UPJ, avoiding the need for excessively inclining the scarred kidney, a maneuver that would result in intrarenal damage and bleeding [66].

CHAPTER 7

Pathophysiology of Urinary Tract Obstruction

Frederick A. Gulmi[1] & Diane Felsen[2]

[1]Brookdale University Hospital and Medical Center, Brooklyn, NY, USA

[2]Weill Cornell Medical College, New York, NY, USA

Introduction

We have been involved with research on the pathophysiology of unilateral (UUO) and bilateral ureteral obstruction (BUO) for the last 25 years. When we first began in this field the literature on the effects of UUO and BUO on the kidney focused mainly on the glomerulus and tubular function. The progression of the vasodilation and subsequent vasoconstriction of the afferent and efferent glomerular arterioles and the ultimate effect this had on renal blood flow, the glomerular filtration rate, and tubular function were initially reported. At that time, measuring effective renal blood flow (eRBF) and inulin clearance, along with the usual parameters of tubular function, would be ample information to report.

This progressed to reporting more information on the hormones, peptides, eicosanoids, and other vasoactive mediators that were circulating, and the effect they had on the intraglomerular vasculature and overall RBF, glomerular filtration, and tubular function.

The focus now is the interstitium, the space between the tubules. UUO is accompanied by changes in the architecture of the kidney. The most prominent interstitial change is fibrosis, and the accumulation of collagens and other extracellular matrix components. Interstitial fibrosis is characteristic of many clinical entities, including diabetes, ureteral obstruction, transplant rejection, and glomerulonephritis. It has been shown in a variety of chronic renal diseases that the presence of interstitial fibrosis is a major determinant of glomerular filtration rate (GFR). Therefore, an understanding of the processes leading to fibrosis could eventually lead to targeted antifibrotic strategies that could allow patients to regain their lost renal function.

In this chapter, we will explore some of the time-tested and older information on the effects of UUO and BUO on the renal glomerulus and tubule. We will present some of the newer concepts regarding the cellular and molecular mechanisms in the development of renal fibrosis. While the information presented will expose the reader to the basics of this information, it will not be a comprehensive review of the subject (for recent reviews, see [1, 2]).

Patient presentation

Symptoms

Urinary tract obstruction can result in a wide range of symptoms, from asymptomatic (incidentally discovered) to the classic picture of renal colic. The symptom complex varies according to (1) the time interval over which the obstruction occurs (i.e. acute or chronic); (2) whether the obstruction is unilateral or bilateral; (3) the etiology of the obstruction (i.e. intrinsic vs extrinsic); and (4) whether the obstruction is complete or partial.

Acute obstruction is usually associated with flank pain that may radiate into the groin and/or ipsilateral thigh. Patients commonly experience nausea, vomiting, and chills. If the renal unit is infected, high fevers may also be present. A patient with high fever, above 101°F, requires emergent urologic intervention and relief of the obstruction. It is more common to have acute UUO than BUO; however, if acute BUO occurs, the patient also

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

may experience a sudden onset of anuria. UUO and BUO can develop over long periods of time, in which case patients are usually asymptomatic, making the diagnosis of obstruction more difficult and, in many cases, incidental. When the obstruction is bilateral and chronic, patients may present with nonspecific complaints of an increase in abdominal girth (pants do not fit), ankle edema, malaise, anorexia, headaches, weight gain, fatigue, and shortness of breath. They may also have symptoms reflective of uremia, such as mental status changes, tremors, and gastrointestinal bleeding. Patients with either a solitary kidney or a nonfunctioning contralateral renal unit can present with UUO and symptoms of uremia.

When the obstruction is unilateral and chronic, the patient may complain of intermittent flank pain during periods of forced diuresis, such as after the consumption of alcohol, a known diuretic. This has been referred to as a Dietl's crisis, after the Polish physician, Joseph Dietl. Classically, the pain is described as a sudden excruciating pain in the kidney caused by distention of the renal pelvis, rapid ingestion of large amounts of liquid, or kinking of a ureter that produces temporary occlusion of the flow of urine from the kidney. If there is hydronephrosis associated with blunt trauma, the presenting symptom can also be gross hematuria. The extrinsic causes of obstruction usually have a more insidious and hence symptom-free presentation, whether they are unilateral or bilateral. These obstructions are usually detected incidentally during the routine clinical work-up of the primary disease process.

A history of the patient's voiding habits is also significant. These can vary from symptoms of a weak and intermittent urine stream, urgency, urgency incontinence, overflow incontinence, and nocturia, to barely any urination at all (i.e. complete obstruction). Finally, patients may also notice rather profound increases in their urine output, out of proportion to their fluid intake, which results from poor renal concentrating ability.

Clinical signs and biochemical findings

The clinical signs of urinary tract obstruction are somewhat nonspecific. Obstruction is occasionally associated with an abdominal mass, usually suprapubic, but it may also be a large flank mass, palpable during physical examination, which on rare occasions can be visible. The patient may also have signs of volume overload, such as bipedal edema, pulmonary congestion, and hypertension. Laboratory data may include hematuria (microscopic and/or gross), proteinuria, crystalluria, pyuria, and urinary casts. When chronic obstruction is the predominant clinical picture, the urinary diagnostic indices are most often similar to those seen with acute tubular necrosis: an elevated urinary sodium concentration, a decreased urine osmolality, and a decreased urine-to-plasma creatinine ratio. If the obstruction is more acute and not accompanied by renal failure, the urinary indices can resemble those of prerenal azotemia: a low urinary sodium concentration and an increased urine osmolality [3]. The serum chemistry studies may demonstrate elevations of serum blood urea nitrogen (BUN) and creatinine, hyperkalemia, and acidosis.

When patients experience acute obstruction in the presence of bacterial urinary tract infection, they may present with signs and symptoms of pyelonephritis or systemic sepsis. Obstruction coexisting with infection is a true urologic emergency, and appropriate imaging studies (excretory urogram, renal ultrasonography or retrograde ureteropyelography) must be performed on an emergency basis. The obstruction must be relieved by either percutaneous nephrostomy or a ureteral stent.

The rationale for immediate relief of obstruction is based upon the physiology of fluid reabsorption during obstruction. After the onset of obstruction there is increased intrapelvic pressure, resulting in pyelolymphatic and pyelovenous urine back flow as well as possible fornix rupture and extravasation [4, 5]. Accordingly, there is direct movement of urine and bacteria into the vascular tree during obstruction, resulting in a life-threatening situation. In chronic obstruction, despite a marked reduction in GFR and RBF [6], urine continues to move into the vascular system [7].

Diagnosis

Excretory urography

For the urologist, the intravenous urogram (IVU) has been the gold standard for the detection of ureteral obstruction in patients with normal renal function and who have no allergies to contrast material and are not pregnant. The urogram can provide both functional and anatomic details of the obstruction, as opposed to ultrasonography, which provides more anatomic detail.

Acute urinary obstruction is visualized on the IVU by (1) the obstructive nephrogram; (2) a delay in filling of the collecting system with contrast material; (3) dilation of the collecting system, possibly with an increase in renal size; and (4) possible forniceal rupture with urinary extravasation [8].

Chronic cases of ureteral obstruction are usually visualized by ureteral dilation, tortuosity, and a standing column of contrast in the ureter to the point of obstruction. The kidney may demonstrate marked parenchymal thinning (either segmental or complete), calyceal crescents, and the soap bubble nephrogram [8]. However, the IVP is rarely performed today in radiology depart-

ments. It has essentially been replaced by the unenhanced CT scan (see below).

Ultrasonography

The renal sonogram is a good starting point for evaluating the renal units of patients who have azotemia, contrast-induced allergy, are pregnant, or are in the pediatric age group. Significant information can be obtained about both the renal parenchyma and the collecting system with no exposure to radiation, or contrast-induced nephrotoxicity or anaphylaxis.

Hydronephrosis will appear as a dilated collecting system separating the normally echogenic renal sinus, creating an anechoic central area surrounded by parenchyma. Echoes within the collecting system may indicate an infection (pyonephrosis), hemorrhage, or a lesion of the transitional mucosa, among other diagnoses. The thickness of the renal parenchyma can be measured as an indicator of the duration of the obstruction; the degree of hydronephrosis should not be equated with the duration of the obstruction.

There are several pitfalls to the use of ultrasonography for diagnosing obstruction. Both the underdiagnosis of hydronephrosis, i.e. missing an obstruction (false negative), and overdiagnosis of obstruction due to the presence of hydronephrosis (false positive) are possible. Sonograms can be false negative as a result of an acute onset of obstruction, an intrarenal collecting system, dehydration, and the misinterpretation of caliectasis for renal cortical cysts. Sonograms can be false positive for obstruction as a result of a capacious extrarenal pelvis, parapelvic cysts, vesicoureteral reflux, and a high urine flow state [8]. Therefore, although an excellent tool for the initial evaluation of selected patients with suspected renal obstruction, the sonogram should be interpreted carefully and must be consistent with the overall clinical picture.

Diuretic renography

The diuretic renogram is becoming more widely utilized than excretory urography for evaluation of the dilated collecting system. It provides a noninvasive measure of the relative renal function and has the ability to wash out the radiopharmaceutical agent from the dilated collecting system. There is a marked reduction in radiation dose in comparison with excretory urography, and there is no potential for contrast-induced nephrotoxicity [9].

The most widely used radiopharmaceutical agents are: (1) tubular tracers: ^{131}I-ortho-iodohippurate (OIH) and ^{99m}Tc-mercaptoacetyltriglycine (MAG3); and (2) glomerular tracers, namely ^{99m}Tc-diethylene triaminepentaacetic acid (DTPA). For evaluating obstruction, the radiopharmaceutical agent of choice today is MAG3, because it is more efficiently extracted by the kidney than is DTPA, delivers a lower dose of radiation to the obstructed kidney than does OIH, and is excreted by the same portion of the tubule that responds to furosemide [9, 10]. MAG3 has been shown to provide better counting statistics and visualization of the anatomy of obstruction than do OIH and other radiopharmaceutical agents [11].

The technique of patient preparation and the timing of the administration of the diuretic, when diuretic renography is performed, are extremely important. The patients should be well hydrated before the procedure. An intravenous line may be started before the procedure [9, 12]. Patients who can void spontaneously do not require bladder catheterization. Those who cannot void spontaneously do require bladder catheterization to: (1) ensure adequate bladder drainage; (2) reduce false-positive results; and (3) decrease the radiation dose to the bladder and gonads. The patient's renal function is extremely important when the results from a diuretic renogram are interpreted. In the presence of a reduced creatinine clearance, it may be necessary to increase the diuretic dose to achieve an adequate flow rate and reduce the possibility of a false-negative result [13].

The timing of the administration of the diuretic after the administration of the radiopharmaceutical agent has been carefully worked out. Brown *et al*. determined that the urinary flow rate is 3.5 mL/min greater at 15–18 min after intravenous furosemide than at 3–6 min after a diuretic (Figure 7.1) [14]. The traditional diuretic renogram is performed by administering the radiopharmaceutical agent and obtaining images, followed 20 min later by intravenous administration of the diuretic, and then measuring the half-life for the clearance of the tracer from the collecting system. O'Reilly *et al*. referred to this technique as the F + 20 diuretic renogram [15, 16]. Figure 7.2 depicts the various outcomes from the F + 20

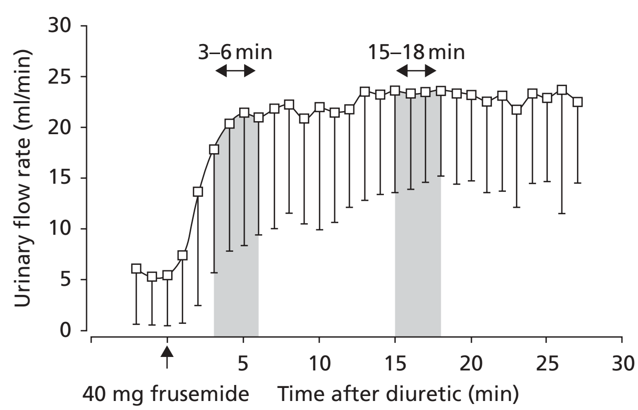

Figure 7.1 Mean urinary flow rates following diuretic injection (error bars indicate standard deviation) (reproduced from Brown *et al. B J Urol* 1992;69:121–125, with permission).

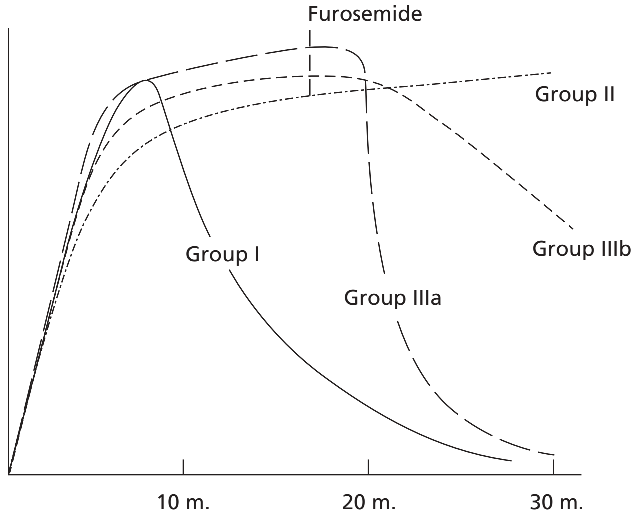

Figure 7.2 Gamma camera renograms obtained from computer generated regions of interest using ^{123}I-ortho-iodohippurate (OIH) demonstrate four responses. Group I is a normal renogram. Since obstruction is sometimes unmasked by diuretic administration, O'Reilly *et al.* recommend a repeat renogram 15 min after diuretic administration. A second group I, normal renogram, excludes obstruction. Progressive accumulation (group II) despite administration of furosemide at about 20 min after tracer injection confirms obstruction. On the other hand, rapid emptying following diuretic administration (group IIIA) despite an initial rise in the renogram curve indicates dilation without obstruction. Finally, an increasing curve with a partial excretory response may indicate either partial obstruction or renal dysfunction with an inability to respond to the diuretic (group IIIB) (reproduced from O'Reilly, P.H., Shields, R.A., Testa, J.H., eds. *Nuclear Medicine in Urology and Nephrology*, 2nd edn. London, England, Butterworths, 1986, pp, 91–108, with permission).

diuretic renogram. Diagnostic dilemma arises with patients who show a partial excretory response; this indicates either an inability to excrete the radioisotope because of poor renal function or a truly partially obstructed system (Group IIIa in Figure 7.2). Upsdell *et al*. were able to convert this equivocal response to the diuretic into a wash-out response by administering the diuretic 15 min before administering the radiopharmaceutical agent, i.e. F – 15 [13]. This is the time it takes for lasix to reach its maximal diuretic effect and thus eliminates "lag-time" as a false positive for obstruction. Some centers routinely use the F – 15 technique for diuretic renography when renal obstruction is suspected. Others use the F + 20 technique for their routine diuretic renograms, reserving the F – 15 technique for use when the F + 20 method demonstrates partial obstruction.

Data from the diuretic renogram can be interpreted either visually or by quantitative measurements of the half-life of the diuretic response [12]. There are many factors that influence the half-life, including: (1) renal function, which includes the level of renal maturity; (2) compliance of the collecting system; (3) volume of the collecting system; (4) hydration of the patient; (5) presence or absence of a bladder catheter; (6) radiopharmaceutical agent; and (7) dose of the diuretic [9, 17]. It is generally accepted that a clearance of the radiopharmaceutical agent from the renal pelvis with a half-life of less than 10 min is normal; some experts consider a half-life of less than 15 min to be normal. Clearance of tracer with a half-life between 15 and 20 min is considered equivocal and a half-life greater than 20 min indicates an obstruction [9, 18].

Whitaker test

The Whitaker test was considered the gold standard for the evaluation of upper urinary tract dilation. It provided urodynamic evidence of a mechanical obstruction of the upper urinary tract at a given flow rate. With the advent of the diuretic renogram and some of the newer radiopharmaceutical agents, the Whitaker test is not often utilized clinically. The Whitaker test is performed with the patient placed on a fluoroscopy table in the prone position. Before the patient is positioned prone, a bladder catheter is placed and connected to a pressure transducer for continuous monitoring of intravesical pressures with changes in renal pressure. A renal cannula (18G) is then inserted and connected to a pressure transducer. A combination of saline and contrast is administered via the renal cannula at a rate of 10 mL/min. Bladder pressure is monitored throughout the procedure and its relationship to changes in renal pressure can be significant. Contrast is given along with the saline, making fluoroscopic monitoring of the anatomic site of the obstruction possible [19].

Results are separated into three categories [20]:

- Pressure less than 15 cmH_2O = nonobstructed;
- Pressures of 15–22 cmH_2O = equivocal;
- Pressures greater than 22 cmH_2O = obstructed.

Because the diuretic renogram is noninvasive and easily reproducible, and provides quantitative evaluation of the split and total renal function with minimal radiation exposure, it is clinically utilized more today than the Whitaker test. However, when there is extreme upper tract dilation and/or poor renal function precluding an adequate diuretic response, the pressure flow study may still have clinical utility.

Duplex Doppler ultrasonography and renal resistive index

The use of duplex Doppler during ultrasonographic evaluation of the kidney allows the determination of the renal resistive index (RI) where [21, 22]:

$$\text{RI} = ([\text{peak systolic velocity}] - \text{lowest diastolic velocity}])/[\text{peak systolic velocity}]$$

A value of 0.70 has been taken as the upper limit of normal [23]. RIs above 0.70 are used for the diagnosis of obstruction, although this diagnosis is not exclusive for obstruction, in as much as medical renal diseases alone can also cause the RI to exceed 0.70. An RI in the obstructed kidney that is 0.1 greater than the RI in the contralateral kidney is considered to be significant enough to indicate obstruction [24].

There is much controversy in the literature regarding the use of the RI in obstruction. Platt *et al*. presented data on 23 patients with acute UUO of 36-h duration or less, measuring the RI index in the "obstructed" and the contralateral renal units [25]. The mean RI in the obstructed kidney was 0.77, as opposed to 0.60 for the normal contralateral kidney. In three obstructed kidneys with an RI of less than 0.70, two had pyelosinus extravasation and one had obstruction for less than 4–5 h. Because the vasoconstriction of UUO occurs after 5–6 h, the RI may not rise until renal obstruction has been present for at least 5–6 h. Platt *et al*. concluded that Doppler determination of renal RIs is a valuable addition for improving the accuracy of routine renal ultrasonography in the diagnosis of renal obstruction in patients presenting with acute renal colic and for whom an IVU is not desirable, e.g. pregnant patients and patients with a history of contrast-induced allergy or renal failure.

Other investigators believe there is no role for duplex Doppler sonography in the detection of acute renal obstruction [22, 26]. Tublin *et al*. evaluated 32 patients with acute renal colic [26]. Twelve of the obstructed kidneys had a mean RI of less than 0.70, and seven of the nonobstructed kidneys had a mean RI of greater than 0.70. Using an RI of greater than 0.70 as diagnostic of acute renal obstruction, they determined that the sensitivity and specificity of duplex Doppler sonography were 37% and 84%, respectively. When using a difference in the RI of greater than 0.10 between the ipsilateral and contralateral renal units to diagnose obstruction, they determined that the sensitivity and specificity were 37% and 100%, respectively.

The difference in clinical findings between the two studies described above may result from several factors, including: (1) the quality of the examination and the Doppler waveform analysis; (2) the duration of obstruction; (3) the presence of a fornix rupture and extravasation; and (4) the degree of obstruction. Finally, Tublin *et al*. pointed out that the initial management of the acute renal colic with nonsteroidal anti-inflammatory drugs (NSAIDs) could alter the intrarenal vascular tone and hence affect the RI [26].

Computed tomography and magnetic resonance imaging

Computed tomography (CT) is an alternative to IVU for patients in whom the immediate use of intravenous contrast without steroid preparation is contraindicated, e.g. patients with allergy to iodinated contrast or shellfish, and patients with asthma, or in patients with elevations in serum BUN and/or creatinine.

Smith *et al*. investigated the use of noncontrast-enhanced CT in the diagnosis of acute flank pain [27]. They compared the findings in 20 patients with acute flank pain on both noncontrast-enhanced CT and IVU. CT and IVU demonstrated ureteric obstruction in 12 patients. In five of the 12, a stone was demonstrated on both studies. Six patients had a stone that was seen on noncontrast-enhanced CT and not on IVU. In one patient, a stone could not be visualized on either study, and no obstruction was demonstrated with either investigation in eight patients. Noncontrast-enhanced CT was performed at either 5- or 10-mm cuts, and all studies were completed within 5 min. Noncontrast-enhanced CT is more sensitive than IVU in the detection of ureteric stones in acute flank pain ($P < .01$). In addition, CT can provide information about extrinsic causes of ureteral obstruction, as well as nonurinary causes for the acute flank pain. Therefore, the patient who is not a candidate for IVU in the emergency room, and yet warrants a diagnosis for flank pain, may be a candidate for noncontrast-enhanced CT scan.

Today, unenhanced helical CT is gaining widespread acceptance in many institutions over conventional CT imaging. The images are obtained faster than conventional CT scanning, often in one breath hold. The axial images can be used to create sagittal and/or coronal reformations, adding to the anatomic detail of the urinary tract and the potential for stone passage. The secondary signs of obstruction on helical CT include: (1) hydroureter; (2) perinephric stranding; (3) hydronephrosis; (4) periureteral edema; and (5) renal swelling [28]. Unenhanced helical CT and conventional CT may not differentiate a uric acid from a calcium stone, necessitating a kidney–ureter–bladder (KUB) X-ray study to differentiate the stone type. However, it has been described that uric acid calculi have lower attenuation values than calcium oxalate calculi, which have very high attenuation values (1000–1570 Hounsfield units). Therefore, the differentiation of stone type is possible on the CT images [28]. It should be noted that stones formed following administration of indinavir (Crixivan) are not detectable on CT [29].

Rothpearl *et al*. investigated the use of magnetic resonance imaging (MRI) for the simultaneous visualization of the entire urinary tract without the use of intravenous contrast or ionizing radiation [30]. For all patients with

urinary tract obstruction, a diagnosis of obstruction was made on the MR urogram. However, in eight patients in whom ureteral calculi was the source of obstruction, there was no visualization of calculi on the MR urogram. This was accomplished by comparing the urogram with a scout radiograph of the kidneys, ureter, and bladder. The point of obstruction was identified in all patients, and other etiologies for obstruction, e.g. intraluminal ureteral neoplasm and ureteral stricture disease, were well visualized. The disadvantages of this technique, in addition to the inability to identify the ureteral calculus, are the image acquisition time of 34 min and the cost of the procedure. Again, for patients with allergies to iodinated contrast and renal failure, this technique may have its place.

Ureteral obstruction

There are a host of diseases that can cause either UUO or BUO (Table 7.1). Most are well known to the urologist.

The experimental models for ureteral obstruction include: (1) unilateral or bilateral ureteral ligation; (2) burying the mid ureter within the psoas muscle; and (3) placing silastic plastic tubing around the ureter to constrict the ureteral lumen.

Unilateral ureteral obstruction

Renal blood flow, glomerular filtration rate, and ureteral pressure

The acute unilateral occlusion of a ureter will result in a characteristic triphasic relationship between RBF and ureteral pressure [31]. The first phase is characterized by a rise in both ureteral pressure and RBF lasting approximately 1–1.5 h. This is followed in phase 2 by a decline in RBF and a continued increase in ureteral pressure lasting until the fifth hour of occlusion. The final phase ensues with a further decline in RBF accompanied by a progressive decrease in ureteral pressure (Figure 7.3). Hemodynamically, phase 1 is characterized by an initial afferent arteriole vasodilation [6] followed by an efferent arteriole vasoconstriction in phase 2 and afferent arteriole vasoconstriction in phase 3 [32]. The third phase of UUO, the vasoconstrictive phase, is characterized by both pre- and post-glomerular vasoconstriction that reduces both RBF and ureteral pressure [31]. Yarger *et al*. demonstrated a marked decrease in the perfusion of the superficial cortical tissue and an increase in the perfusion of juxtamedullary glomeruli after 24 h of UUO [33]. In addition, effective renal plasma flow (eRPF) was shown to be 55% of control values in the obstructed kidney after 24 h of UUO [34]. Utilizing the injection of microspheres during ureteral occlusion, they also demonstrated an increase in intrarenal blood flow to the juxtamedullary nephrons, with a corresponding decrease in blood flow to the outer cortical nephrons. They believed that an increase in renin in the outer cortex relative to the inner medulla may explain the shift in intrarenal blood flow [34]. Glomerular cast studies show the poor glomerular perfusion that accompanies UUO (Figure 7.4). Arendshorst *et al*. confirmed with micropuncture studies that changes seen in the whole kidney by 24 h of UUO are found at the single nephron level in association with afferent arteriolar vasoconstriction [35]. Studies using a continuous infusion of 51-chromium-ethylenediamnietetra-acetic acid (^{51}Cr-EDTA), which allow direct measurement of GFR during obstruction, show a 75% decrease in GFR after the onset of UUO [36].

The initial increase in RBF, which has been well characterized in the dog and rat [37], may not occur in all species. In studies in the pig, which has a multicalyceal kidney similar to humans, there is a continuing decline in RBF after onset of UUO [36]. In baboons, 12 h of UUO was not accompanied by a significant change in RBF [38]. In the 4-week old lamb, RBF was stable for 5 h after onset of UUO, and declined to 71% of baseline at 5 days [39]. It is not known if the difference in the RBF response is due to the presence of a multicalyceal kidney or other factors.

Although the physiologic changes characteristic of phase I and III of UUO have been known for some time, studies are still underway to understand the underlying cellular and molecular changes. Early studies invoked local physical interactions to explain changes in afferent and efferent arteriolar tone. Table 7.2 summarizes the effects of the various mediators on afferent and efferent glomerular arteriolar tone. However, it soon became clear that biochemical mediators were responsible for a substantial portion of these changes. Numerous studies have been carried out to determine the role of eicosanoids (prostaglandins and thromboxane), angiotensin II, nitric oxide, and endothelin in the acute and chronic changes in RBF.

Tubular changes

Several studies suggested that the increased excretion of water and salt after UUO occurs in either deep nephrons or the collecting duct of superficial nephrons [40–42]. However, Buerkert *et al*. were able to show with micropuncture studies that the collecting duct's ability for reabsorption and its permeability to water were not altered by acute ureteral occlusion [43]. Therefore, the more likely location for the increased sodium excretion is the deep juxtamedullary nephron.

Jaenike and Bray were able to produce a concentrating defect in the unilaterally obstructed kidney after only 6

min of ureteral occlusion [44]. Kessler demonstrated a concentrating defect in the obstructed kidney within 5–8 min of ureteral occlusion [45]. The administration of large doses of antidiuretic hormone (ADH) restored the concentrating ability and the papillary chloride concentration in saline-loaded animals. This observation is contrary to that of other investigators, who have found the concentrating defect in the ipsilateral kidney of UUO to be ADH resistant. Solez *et al*. observed a marked decrease in urine osmolality in dehydrated rats after

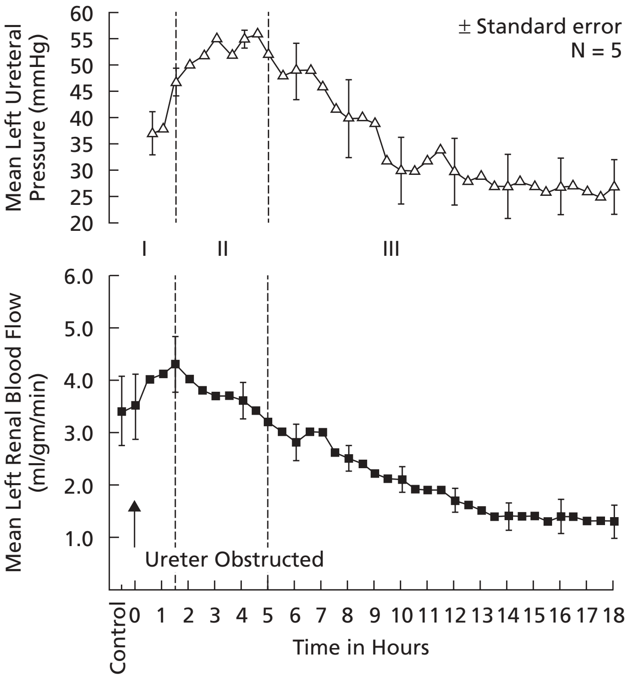

Figure 7.3 Triphasic relationship between ipsilateral renal blood flow and left ureteral pressure during 18 h of left occlusion. The three phases are designated by Roman numerals and divided by vertical dashed lines. In Phase I, renal blood flow (RBF) and ureteral pressure rise together. In Phase II, the left RBF begins to decline; ureteral pressure remains elevated and, in fact, continues to rise. Phase III shows the left RBF and pressure declining together (reproduced from Moody *et al*. [31], with permission).

relief of 18 h of UUO, not in association with a concomitant increase in urine output [46]. They found a significant decrease in inner medullary plasma flow during 18 h of UUO, and the flow increased after the release of ureteral occlusion. Histologic study revealed necrosis of both the inner and outer medullae. This physical effect of obstruction on the medulla may result in a decreased ability of the post-UUO kidney to concentrate urine.

Wilson examined the effect of volume expansion on post-UUO renal function and found a significant increase in free water clearance from the obstructed kidney in association with an increase in urine flow rate [47]. Wilson concluded that volume expansion was enhancing an already-present defect in water reabsorption either in distal nephrons and/or deep nephrons or in collecting ducts of the obstructed kidney. Hanley and Davidson also described an inability of the kidney to concentrate urine after obstruction [48]. This inability was associated with an inability of the cortical collecting tubule to respond to either ADH (vasopressin) or cyclic adenosine monophosphate (cAMP) stimulation; there was a 76% reduction in the response of the collecting tubule to either stimulus. There is an increase in prostaglandin E1 (PGE_1) production with UUO, and it is known that PGE_1 can inhibit the tubular effects of vasopressin, increasing free water losses from the post-UUO kidney [49].

The characterization of the aquaporins, a family of membrane water channels, provides a molecular basis for transmembrane water movement [50]. Aquaporin-2 is the predominant vasopressin-sensitive water channel of the collecting duct. Frokiaer *et al*. have examined changes in aquaporin expression in UUO [51]. There was a 77% decrease in aquaporin expression with 24 h of UUO, which persisted for at least 24 h after release of UUO. Consistent with the decreases in aquaporin was a greatly increased free water clearance in the obstructed kidney.

The kidney has an impaired distal hydrogen ion secretion after obstruction. This is seen as a lack of an increase in carbon dioxide partial pressure (PCO_2) during bicarbonate loading, as well as impaired urinary acidification with the administration of sodium sulfate. The postobstruction kidney has a higher bicarbonate reabsorption rate than the contralateral kidney [52]. Walls *et al*. also demonstrated a low urinary PCO_2, during bicarbonate loading, in the post-UUO kidney in comparison with the contralateral kidney, as well as an elevation in urinary pH from the postobstruction kidney [53].

After the release of UUO, the fractional excretion of phosphate is markedly decreased in the obstructed kidney (3.4%), whereas it is increased in the control kidney (35.3%). This is accompanied by a twofold greater fractional excretion of sodium in the obstructed kidney than in the control kidney. However, the decrease in phosphate excretion is believed to be secondary to a decreased filtered load of phosphate. The increased excretion of salt and water is secondary to a decreased reabsorption in the distal nephron without a concomitant decrease in proximal reabsorption [54].

Harris and Yarger described a marked decrease in urinary potassium excretion from the ipsilateral kidney after 24 h of UUO [55]. Yarger and Griffith found a decrease in both the absolute and fractional excretion of potassium after 24 h of UUO with micropuncture studies [33]. This suggests that the decrease in potassium excretion does not result from a decrease in the filtered load of potassium. Explanations for the decrease in potassium excretion would be that the distal tubular volume flow rate is low after UUO, the amount of sodium passing through the distal nephron is also decreased during UUO, and the normal potassium secretory mechanism has been directly interfered with as a result of mechanical obstruction. These explanations are supported by the work of Thirakomen *et al*. who showed a persistent decrease in absolute potassium excretion despite volume expansion or sodium sulfate administration [52]. These two maneuvers increase distal sodium delivery, but they do not increase the excretion of potassium; this action lends support to the hypothesis of a defect in the distal secretory mechanism of potassium as the cause of the decreased excretion of potassium from the post-UUO kidney.

Bilateral ureteral obstruction

Renal blood flow, glomerular filtration rate, and ureteral pressure

The triphasic pattern of RBF and ureteral pressure changes that characterizes UUO is not seen after BUO or unilateral obstruction of a solitary kidney. RBF increases after the first 90 min of BUO, as it does with UUO [56]. However, between 90 min and 7 h of BUO, the RBF is significantly lower than the RBF during the same time interval of UUO (Figure 7.5A). The decrease in RBF is accompanied by an increase in renal vascular resistance during BUO to a greater level than with UUO (Figure 7.5B). However, by 24 h of BUO, the RBF is as low and renal vascular resistance as high as with 24 h of UUO (Figure 7.5A, B). However, ureteral pressure is higher than in UUO (Figure 7.5C). Gulmi *et al*. found eRBF to be markedly decreased even at 48 h of BUO [57]. After release of BUO, the RBF remained significantly decreased in comparison with preobstruction values for 11 h of the study. Jaenike showed that the distribution of RBF after BUO is much different from that in the UUO model [58]. Using radioactive microspheres, he showed that 55% of RBF remains in the cortical nephrons and only 14% is shifted to the innermost renal zones. Yarger *et al*. used micropuncture studies to demonstrate a decrease in both whole kidney as well as single nephron clearance of para-aminohippurate (PAH) (17% and 55%, respectively) [59]. Solez *et al*., using intravenous [^{125}I]-albumin infusion, showed a marked decrease in inner medullary plasma flow to 8% of normal by 18 h of BUO [46].

Ureteral pressure follows a similar pattern for the first 4½ h of both BUO and UUO, i.e. a progressive rise in pressure (Figure 7.5C). However, after 4½ h of BUO, the ureteral pressure remains elevated until 24 h, whereas in UUO, ureteral pressure begins to progressively decline to control levels by 24 h of ureteral occlusion (Figure 7.5C). This increase in ureteral pressure has been documented to at least 48 h after BUO [57]. Dal Canton *et al*. demonstrated an increase in intratubular pressure from 14.1 to 28.9 mmHg ($P < .005$) with micropuncture studies in rats after 24 h of BUO [60]. This change in intratubular pressure caused a decrease in the hydrostatic pressure gradient from 31.7 to 20.0 mmHg and a decrease in the effective filtration pressure at the afferent end of the glomerulus from 16.6 to 5.4 mmHg ($P < .001$). Yarger *et al*. also measured both proximal and distal tubular pressures during micropuncture studies of rats after 24 h of BUO and found the pressures to be 30 and 27.7 mmHg, respectively, in comparison with 9.2 and 6.5 mmHg,

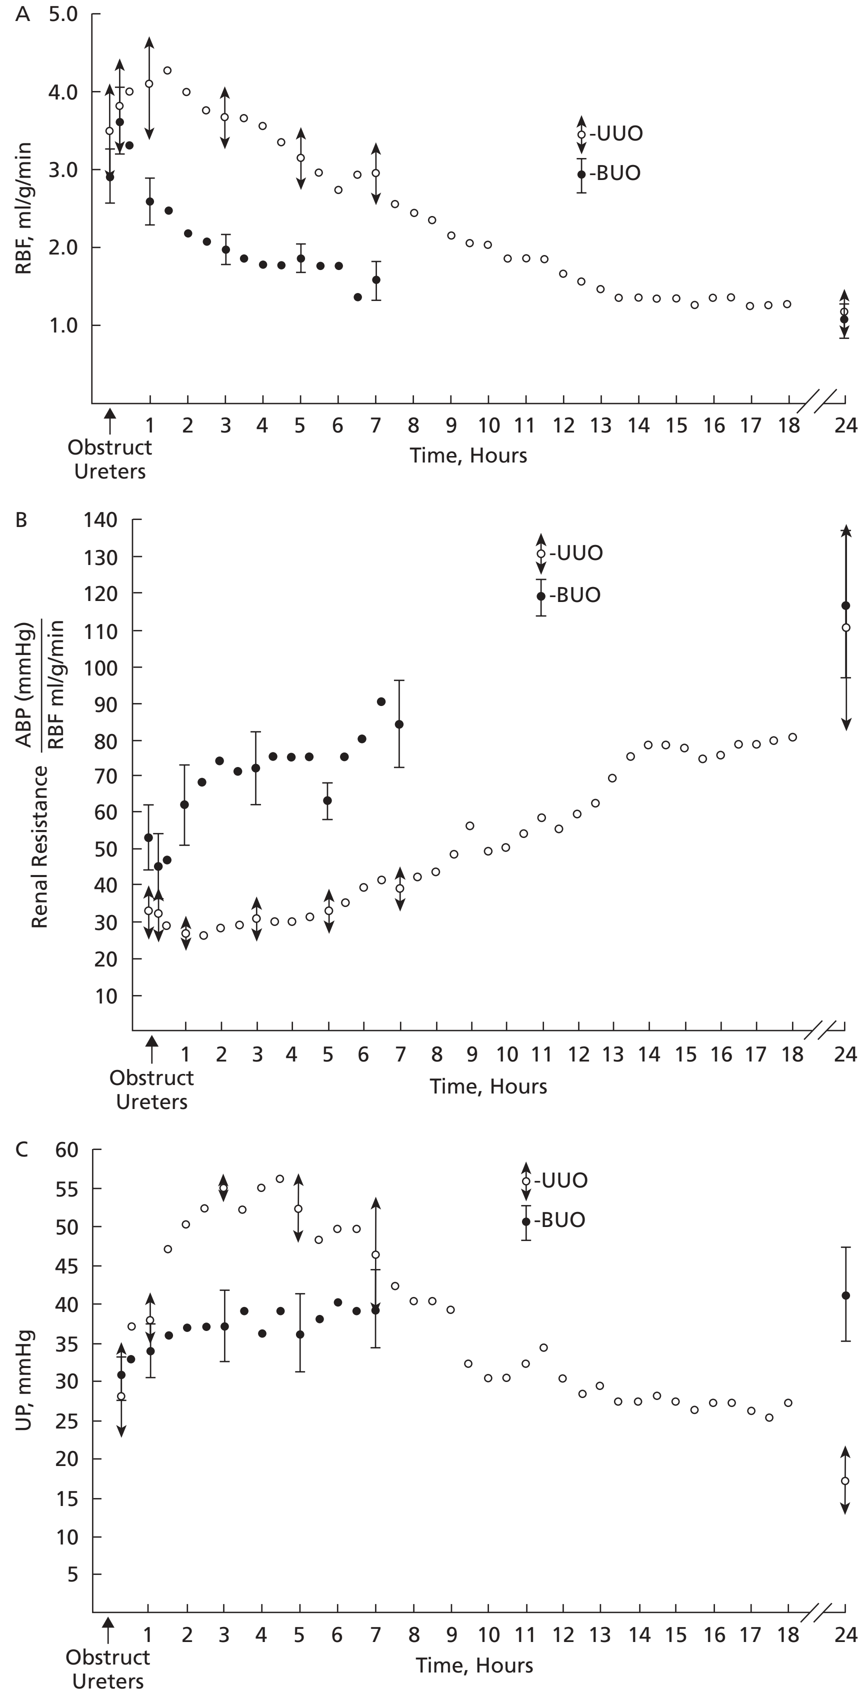

Figure 7.5 Comparison of renal blood flow (RBF) in unilateral ureteral occlusion (UUO) and bilateral ureteral occlusion (BUO), demonstrating a similar pattern of change over the 24-h period, although the RBF in the BUO model is below that of the UUO model from 1½ to 7h postobstruction.
(B) Comparison of the renal resistance (RR) in UUO and BUO demonstrating similar changes over the 24-h period with the RR in the BUO model being higher than in the UUO model in the early hours, corresponding to the lower RBF at that time in BUO.
(C) Comparison of ureteral pressure (UP) in UUO and BUO demonstrating significant difference in the UP at 24h postobstruction.

respectively in UUO rats ($P < .001$). The micropuncture studies of both groups have confirmed what other investigators have observed from the monitoring of ureteral pressure, a rise after 24 h of BUO. Therein lies one of the differences between BUO and UUO. BUO passes through a phase of preglomerular vasodilation and then a postglomerular vasoconstriction and remains in this state. This explains the progressive and persistent rise in ureteral pressure despite a decrease in RBF and an increase in renal vascular resistance. In contrast, during UUO, the kidney passes through three phases: preglomerular vasodilation, postglomerular vasoconstriction, and, finally, preglomerular vasoconstriction (see above).

The GFR after 48 h of BUO is significantly decreased (22% of control values) in comparison with preobstruction GFR [57]. This decrease was also seen by Jaenike in rats after 24 h of BUO; the GFR was reduced to 20% of the control value [58]. With micropuncture studies, Jaenike also found single nephron GFR (SNGFR) to be 34% of normal [58]. However, Yarger and Harris showed that the number of functioning nephrons, as well as the GFR of those functioning nephrons, is higher for kidneys after BUO than after UUO [61]. Harris and Yarger also demonstrated that 84% of superficial and 49% of juxtamedullary nephrons filter after 24 h of BUO, as opposed to 40% of superficial and 12% of juxtamedullary nephrons after 24 h of UUO [32].

Dal Canton *et al*. performed micropuncture studies on rats after 24 h of BUO [60]. They observed a decrease in SNGFR after release of BUO to 40% of normal, secondary to an increase in intratubular pressure from 14 to 30 mmHg. There was little change in glomerular capillary pressure (46 and 50 mmHg, pre- and post-obstruction, respectively). With relief of obstruction, there was a 52% increase in afferent arteriole resistance, resulting in a low SNGFR in the postrelief period. Therefore, in both BUO and UUO, there is a decline in SNGFR after 24 h of ureteral occlusion. In UUO this is secondary to an increase in afferent arteriolar resistance, whereas in BUO it is secondary to a rise in intratubular pressure with little change in afferent arteriolar resistance (Table 7.3).

Table 7.3 Comparison of the effects of unilateral ureteral (UUO) and bilateral ureteral obstruction (BUO) in glomerular hemodynamics (from Dal Canton *et al*. [60]).

	P_T	P_G	AAPF	R_a	SNGFR
24-h UUO	===	↓	↓↓	↑↑	↓↓
24-h BUO	↑↑	===	===	===	↓↓

AAPF, afferent arteriole plasma flow; P_T, intratubular pressure; P_G, hydrostatic pressure across glomerular capillaries; R_a, resistance of single afferent arteriole; SNGFR, single nephron glomerular filtration rate.

Involvement of atrial natriuretic peptide

Several investigators have postulated the accumulation of a "substance" during BUO that would affect the glomerular hemodynamics in such a way that there would be preglomerular vasodilation and postglomerular vasoconstriction, as seen with late-phase BUO. This substance would not accumulate during UUO, because it could be excreted by the contralateral kidney. Wilson and Honrath demonstrated such a substance with cross-circulation studies in rats [62]. When the cross-circulation was between a donor rat with 24 h of BUO and a normal recipient rat, there was an immediate increase in both sodium and water excretion. This did not occur when the donor rat was subjected to 24 h of UUO (Figure 7.6).

Harris and Yarger also postulated the existence of a circulating diuretic factor that accumulated only during BUO [55]. They observed an increase in urine flow and sodium excretion after relief of BUO, UUO with contralateral nephrectomy, or UUO with the continuous intravenous reinfusion of urine from the contralateral kidney. In contrast, the UUO-alone animals did not have postobstructive diuresis and natriuresis.

The discovery of atrial natriuretic peptide (ANP) paved the way for studies on the role of ANP in BUO. ANP has several physiologic effects, including vascular smooth muscle relaxation, i.e. vasodilation, natriuresis, and diuresis. The natriuretic and diuretic actions of ANP have been shown to be caused by: (1) an increase in GFR through afferent arteriole vasodilation and efferent arteriole vasoconstriction; (2) an increase in glomerular capillary ultrafiltration coefficient (Kf); and (3) inhibition of the glomerular–tubular feedback mechanism [63]. These glomerular hemodynamic effects point to ANP as the circulating diuretic and natriuretic substance postulated by previous investigators to explain the observed changes in RBF, ureteral pressure, and glomerular filtration during BUO.

Fried *et al*. demonstrated an elevated level of plasma ANP in rats after 24 h of BUO , but not after 24 h of UUO (393 vs 261 pg/mL;, $P < .01$) [64]. Purkerson *et al*. have shown plasma ANP levels of 400 pg/mL in rats with 24 h of BUO, in comparison with 71 pg/mL in rats with UUO ($P < .01$) and 81 pg/mL in controls ($P < .01$) [65]. Elevated ANP has also been demonstrated in patients with either BUO or UUO of a solitary kidney, or in volume-replete dogs after 48 h of BUO [57, 66].

With the demonstration of elevated levels of ANP in BUO, it became clear that ANP was likely the factor previously postulated by Wilson and Honrath [62] and Harris and Yarger [55]. The stimulus for the elevated

plasma ANP seems to be an increase in intravascular volume, as determined by an elevation in pulmonary capillary wedge pressure (PCWP) and body weight in volume-replete dogs with BUO [57]. In support, clinical studies in patients on chronic hemodialysis show that intravascular volume, and not the degree of renal failure, is the stimulus for an elevation in their plasma ANP levels.

Other mediators

Reyes *et al*. have examined the role of NO in BUO [67]. When N-NAME, an L-arginine antagonist, was infused, there was a further decrease in GFR and eRPF compared to controls, suggesting that NO was maintaining GFR and eRPF during BUO. This was confirmed by showing that there was an improvement in GFR and eRPF, as well as a decrease in renal vascular resistance with the infusion of L-arginine into rats with unilateral release of 24 h of BUO. Other factors may also be involved in BUO. Reyes and Klahr demonstrated that antibodies to either platelet activating factor, endothelin, or vasopressin can ameliorate changes in GFR and eRPF either during or after release of BUO [68–70].

Tubular changes

There are differences between tubular function after release of BUO and UUO (Table 7.4). Several investigators have described marked diuresis and natriuresis after the relief of either BUO or UUO of a solitary kidney in humans [66, 71–74]. Maher *et al*. described a significant increase in urine volume and sodium excretion after relief of obstructive uropathy [72]. The urinary flow more closely followed the osmolar excretion than the sodium excretion in this patient study. The predominant urine solute during this osmotic diuresis was urea, accounting for 37–68% of the total urine osmolality. When serum urea returned to normal, the diuresis ceased. Maher *et al*. therefore postulated that the physiologic diuresis was caused by a high serum urea concentration, which ceased when the BUN returned to normal.

Muldowney *et al*. measured total exchangeable sodium to determine whether the postrelease natriuresis of BUO is pathologic or merely a physiologic elimination of excess body sodium [75]. They found that patients with chronic obstructive uropathy had an increase in total exchangeable body sodium before release of obstruction. After relief of the obstructive uropathy, total exchangeable body sodium levels returned to normal within 2–3 weeks. The loss of sodium in the urine did not result in clinical sodium depletion in any of the patients. Muldowney *et al*. concluded that the increased loss of sodium in the urine upon release of chronic obstructive uropathy is a physiologic reduction of excess body sodium to normal levels.

Gulmi *et al*. described nine patients with obstructive uropathy and postobstructive diuresis and natriuresis [66]. Patients with obstruction had a significantly elevated plasma ANP, in comparison with the control group of patients (Figure 7.7). There was an increase in both absolute and fractional excretion of sodium that subsided with improvement in renal function. This natriuresis and diuresis was associated with an elevation of serum ANP in all patients, which decreased as water and salt excretion decreased (Figure 7.7). Because ANP is a known diuretic and natriuretic, it may be one of the main factors causing the loss of water and salt in the postobstructive state.

In animals, the release of BUO is accompanied by profound diuresis and natriuresis as well. There seems to be a dual mechanism for the increase in water and

Table 7.4 Differences in tubular function after release of unilateral and bilateral ureteral obstruction (24 h).

	Control	Unilateral	Bilateral
Postobstructive diuresis		Absent	Present
Percent of filtration excreted (V/GFR)	1%	Decreased to 0.5%	Increased to 18%
Na^+ excretion fraction filtered			
Proximal tubular reabsorption		Decrease	Decrease
Distal tubular reabsorption			Decrease
Proximal fraction reabsorption	58%	74%	46%
Distal fraction reabsorption	12%		34%
Fraction K^+ excreted	12.3%	Decreased to 7%	Increased to 90%
Concentration U:P	7.6	1.35	1.47

GFR, glomerular filtration rate; P, plasma; U, urine; V, volume.

sodium loss after release of BUO. Yarger *et al*. investigated the site of impaired tubular reabsorption of sodium in surface nephrons with micropuncture techniques [59]. They observed impaired fractional sodium reabsorption in the distal tubule, with normal fractional reabsorption of sodium in the proximal tubule. Jaenike confirmed a postobstructive diuresis and natriuresis in rats after the release of BUO [58]. He also demonstrated that exclusion of sodium intake after obstruction did not decrease the postrelief diuresis and natriuresis of BUO. This contradicts the conclusion of Muldowney *et al*. in human studies [75], that postobstructive diuresis and natriuresis are appropriate responses to increased total body sodium accumulated during obstruction. Jaenike infused urea into normal rats and into rats after relief of UUO to achieve levels of urea similar to those observed in rats with BUO [58]. This caused no increase in salt and water excretion. Therefore, the postobstructive natriuresis and diuresis do not seem to be secondary to an increased solute load. Jaenike did demonstrate a defect in sodium transport in the distal tubule and suggested that this defect is a direct mechanical effect of obstruction at the distal tubule.

McDougal and Wright also described an increase in sodium and water excretion that lasted for 24–36 h after relief of 30-h BUO in rats [76]. However, they observed a reduction in sodium and water reabsorption in both the proximal and distal nephrons. They also observed increased permeability in the tubule wall to both mannitol and inulin. Because there is increased permeability of the tubule after 30 h of obstruction, it is likely that sodium and other ions have increased permeability, thus elevating their tubular fluid concentration by increasing sodium backflux into the tubule. However, this permeability defect existed only after BUO and not UUO; therefore, it seemed unlikely that a permeability

change should occur only when both kidneys are obstructed. McDougal and Wright suggested the possibility that the accumulation of a substance during BUO is a cause of the permeability defect [76].

Fried *et al*. reported experiments in which animals with UUO were compared with two groups of animals with BUO [64]. One group was given access to water after relief of BUO, and one was not. Elevation of plasma ANP and postobstructive diuresis was found in both groups of rats with BUO, but not in rats with UUO. The two BUO groups lost weight before the relief of BUO, and both groups still demonstrated elevated levels of ANP. Fried *et al.* postulated decreased renal excretion and/or metabolism or enhanced atrial production of ANP to explain the elevated ANP levels during BUO. However, the acute weight loss seen in these animals should not be associated with volume expansion and consequently atrial stretch. Because atrial stretch is the main stimulus for ANP, this does not seem to be the explanation.

Gulmi *et al*. produced BUO in dogs, a larger animal model, allowing the invasive monitoring of PCWP in addition to weight loss or gain during BUO [57]. The BUO animals were subdivided into a volume-replete group given normal saline during the 48 h of obstruction and a second group not given intravenous saline after ureteral occlusion. Before release of obstruction, the volume-replete group demonstrated significantly elevated plasma ANP levels in comparison with preobstruction values. This was not seen in the BUO without saline group (Figure 7.8). The elevation of ANP was accompanied by elevations in both PCWP and weight gain in the volume replete BUO group. The BUO group not given normal saline did not have an elevation in PCWP, nor did the animals gain weight. However, both groups of animals did achieve equivalent decrees of renal failure by 48 h of BUO.

The data strongly suggest that the intravascular volume status during BUO, not the degree of renal failure and consequent inability of the kidney to excrete and/or metabolize ANP, leads to the elevation of ANP via atrial stretch. This has been borne out by clinical studies in chronic renal failure patients on hemodialysis showing that the patient's intravascular volume status, measured by PCWP and body weight, determined the level of plasma ANP and not the degree of renal failure [77, 78]. Upon relief of obstruction, both groups of BUO animals exhibited diuresis and natriuresis. However, the group with an elevation of ANP demonstrated prolonged excretion of sodium and water, in comparison with the BUO group, without an increase in plasma ANP. Therefore, an elevated plasma ANP may not be required to achieve the diuresis and natriuresis observed after the release of BUO. A direct effect of obstruction on the tubule itself may contribute to the enhanced excretion of sodium and water of BUO, as suggested in previous studies [58, 76, 79].

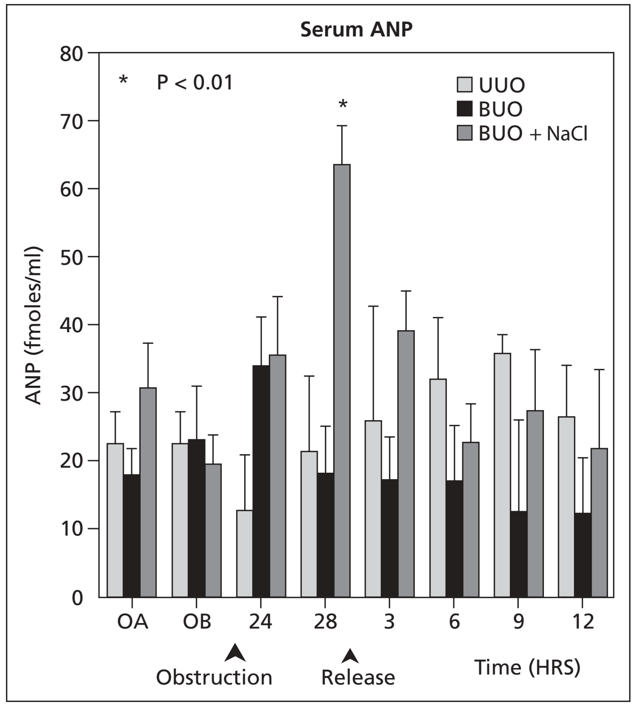

Figure 7.8 Atrial natriuretic peptide (ANP) in all groups both before and after release of 48-h obstruction. OA, preclearance time zero; OB, postclearance time zero (reproduced from Gulmi *et al*. [57], with permission.

There is an enhanced increase in potassium excretion after release of BUO [76, 79]. There is an increase in both the absolute potassium excretion as well as the fractional excretion of potassium [61, 80]. The increase in the delivery of sodium, the tubular fluid flow rate, and plasma potassium are important stimuli for the enhanced excretion of potassium after the release of BUO [40, 61].

There is an impaired ability to acidify the urine and lower the pH in response to an acidemia during BUO. This is believed to be secondary to an inability to secrete hydrogen ions against a gradient. The decrease in the tubular reabsorption of sodium distally may contribute to the inability of the kidney to excrete hydrogen ions.

In the postrelief BUO kidney, the ability to concentrate urine is impaired. There is an increase in free water clearance (C_{H2O}) after release of BUO. This is accompanied by an overall increase in total solute excretion (Cosm) [66, 76]. The major sites affected are the loop of Henle, distal tubule, and collecting duct, mostly from the juxtamedullary nephrons [3]. The mechanisms most often proposed to explain the decrease in concentrating ability in the kidney after obstruction are an inability of the medullary interstitium to maintain its hypertonicity and an insensitivity of the tubule to vasopressin [3]. The

inability to establish the medullary tonicity necessary to concentrate urine comes from the inability of the thick ascending limb of the loop of Henle to reabsorb sodium after obstruction [48]. This ultimately decreases the tonicity in the medullary interstitium and, consequently, the reabsorption of water. Hanley and Davidson demonstrated a significant decrease in the response of the cortical collecting tubule to vasopressin [48]. This was also observed in ligated–deligated rats, which showed no changes in either $U_{Na}V$ or $U_{osm}V$ measured before and after the administration of vasopressin [76].

Interestingly, the highest density of ANP receptors in the nephron is found in the inner medullary collecting duct [63]. Several investigators have demonstrated that ANP can inhibit both sodium chloride absorption in the inner medullary collecting duct [81, 82], and vasopressin-stimulated osmotic water permeability in the same segment of the nephron [81]. These factors have previously been invoked to explain the concentrating defect in postobstruction renal function. Therefore, ANP elevated during BUO may be either the primary cause for a concentrating defect in obstructive uropathy or a contributing factor enhancing an already diminished ability of the kidney to concentrate urine in the postobstruction period. This information is summarized in (Figure 7.9).

Studies have shown that changes in aquaporins can be documented in BUO. BUO for 24 h caused a decrease in aquaporin-2 expression in the inner medulla to 26% of control; 48 h after relief of BUO, the reduction in aquaporin expression persisted. Seven days after the release of BUO, renal excretion of water and electrolytes had returned almost to normal. There was only a partial reversal of the decrease in aquaporin-2 at that time, which coincided with a decrease in the urinary concentrating ability (in response to an 18-h period of thirst). Thus, changes in aquaporin-2 may also be involved in the changes in concentrating ability after BUO [83].

Fibrosis in unilateral ureteral obstruction

Gross changes in the human kidney

The appearance of the kidney after ureteral obstruction varies with the presence of an intrarenal versus extrarenal collecting system, with the length and degree of obstruction, and the presence or absence of infection. The presence of the renal parenchyma completely around an intrarenal collecting system limits its ability to dilate. Expansion of an extrarenal collecting system, however, is not limited by the renal parenchyma. Therefore, the intrarenal system, although obstructed to the same degree and duration as the extrarenal system, may not exhibit the same degree of hydronephrosis; however, the degree of renal damage may be worse.

Acute complete ureteral occlusion may cause little change in the collecting system, especially if there is an intrarenal collecting system; it may take several days to develop significant collecting system dilation under these conditions. Chronic obstruction can produce an enlarged, normal, or atrophic kidney, again depending on the length and degree of obstruction, as well as the presence of an intra- or extra-renal collecting system [8]. Usually the collecting system will dilate with time, especially with extrarenal collecting systems, resulting in gradual compression of the renal papilla. Over time, the collecting system will enlarge to the point that the tissue between the calyces will thin, resulting in calyceal enlargement. Ultimately, the calyces will coalesce, with

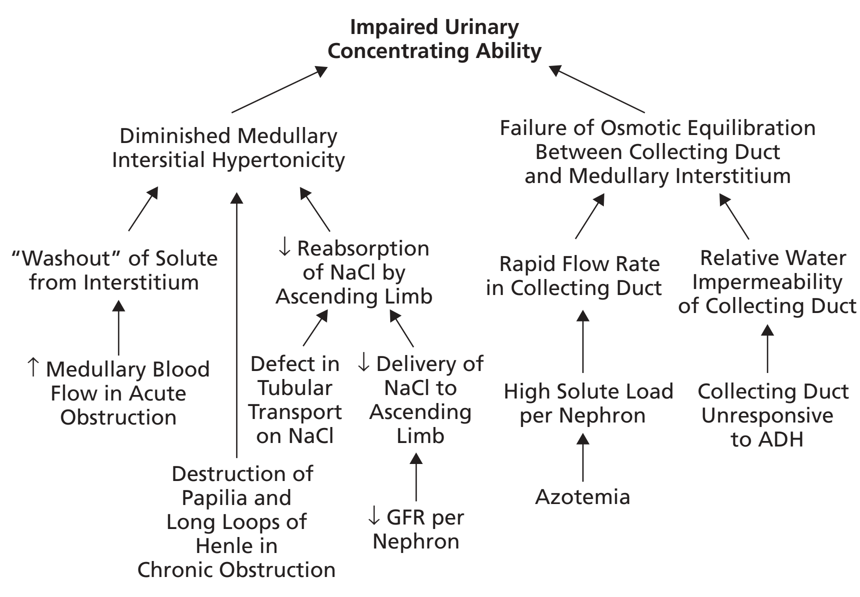

Figure 7.9 Mechanisms by which urinary tract obstruction may impair urinary concentrating capacity of the kidney (reproduced from Walsh *et al.*, Campbell's Textbook of Urology, 8th edition, 2002).

thin septa between them and a "rim" or "shell" of parenchyma remaining peripherally.

Microscopic changes in the kidney: experimental

Initially most of the microscopic changes are confined to the tubules with little effect on the glomeruli [84, 85]. The glomeruli seem relatively resistant to change, except for a slight increase in size and a thickening of Bowman's capsule. The development of hyalinization and connective tissue proliferation are not seen until 231 days of ureteral ligation, and only in relatively few glomeruli [84]. The tubules initially undergo dilation of the lumen with flattening of the epithelium. After approximately 21 days of obstruction, there are barely discernible tubules in several areas of the renal parenchyma on microscopic section.

Fibrosis

Nagle and Bulger used electron microscopy and described the appearance of collagen fibers in the kidney by 7 days after UUO, with an increase up to 32 days [86]. At 32 days, diffuse interstitial collagen was found in the cortex and outer medulla. Sharma *et al.* studied the immunohistochemical localization of collagen subtypes and used *in situ* hybridization to localize collagen mRNA in rabbits with 16 days of UUO [87]. In these studies, interstitial volume was increased, as well as interstitial collagen III and IV, and fibronectin. Increases in collagen I were only in focal, peritubular accumulations.

Collagen is visualized by blue staining in trichrome-stained slides. Specific collagen subtypes have been localized immunohistochemically in rats studied from 1 to 28 days after UUO. Increases in cortical and medullary interstitial space were found; these changes were significant by 7 days after UUO. Collagen III was increased by 3 days in both the cortex and medulla, and medullary collagen was further increased by 7 days after UUO. Prominent changes in collagen I were detected at 14 days after UUO. Collagen IV, laminin, and fibronectin also showed prominent changes by 3 days; these components continued to increase through 14 days. Glomerular fibrosis was not prominent, with only small changes in collagen I being found after 14–21 days of UUO [88].

Despite the relative sparing of the glomerulus from fibrosis, there is a clear decline in glomerular filtration in the obstructed kidney. This is consistent with the finding in a variety of chronic renal diseases, that the presence of interstitial fibrosis is a major determinant of GFR [89–91]. There are several possible reasons for this finding. Tubular atrophy can result in atubular glomeruli; these glomeruli, which are detached from their corresponding proximal tubules, are unable to filter properly [92]. The accumulation of extracellular matrix can isolate tubules from their oxygen supply and may also result in obliteration of peritubular capillaries, which can also result in decreased GFR [93–95].

Central to the fibrotic process is the fibroblast, or its activated form, the myofibroblast. It has long been known that there is an increase in fibroblasts in the obstructed kidney [86, 96, 97]. The transformation of fibroblasts to myofibroblasts [identified by α-smooth muscle actin (SMA) expression] was demonstrated as early as 1973 in a classic paper by Nagle *et al*. [98]. The source of the fibroblasts and myofibroblasts has been the subject of intense research over the last 15 years. Much evidence has been presented that epithelial–mesenchymal transdifferentiation, the process by which renal tubular epithelial cells become (myo)fibroblasts, is a major factor in the development of fibrosis [99]. This will be discussed below. However, not all the recent literature supports this claim. The resolution of these differences will be important in targeting future therapies.

As of this time, there are at least six different cell types which have been implicated in the increase in fibroblasts and/or myofibroblasts in UUO [100] (Figure 7.10). The cell types include: (1) local fibroblasts; (2) tubular epithelial cells; (3) endothelial cells; (4) bone marrow cells; (5) renal progenitor cells; and (6) pericytes/perivascular fibroblasts.

Local fibroblasts

Despite the fact that there are resident fibroblasts in the kidney, their contribution to fibrosis was largely unstudied. Picard *et al*. used immunofluorescence and electron microscopy to examine this issue [101]. They found an increase in α-SMA in resident fibroblasts as early as 1 day after UUO. Furthermore, they showed a decrease in 5′-nucleotidase, a marker of fibroblasts., with progression of UUO. This demonstrates activation of resident fibroblasts to myofibroblasts in UUO.

Tubular epithelial cells

In the epithelial–mesenchymal transition (EMT), epithelial cells undergo transdifferentiation to fibroblasts or myofibroblasts. *In vitro*, it has been shown that tubules can be transformed into cells with a myofibroblastic phenotype. Many studies have demonstrated that incubation of renal tubular epithelial cells with varying doses of the profibrotic cytokine transforming growth actor-β (TGF-β) causes the following changes [102, 103]:

- The typical cobblestone appearance of cells in culture is replaced by the elongated spindle shape associated with fibroblasts.
- Using scanning electron microscopy, the cells are shown to lose their apical–basal polarity and cell surface

microvilli. The apical–basal polarity is replaced by a front end-back end-fibroblast-like polarity with cytoplasmic projections at the front end.

• Under transmission electron microscopy, large bundles of actin microfilaments and dense bodies are seen.

• The presence of α-SMA in the TGF-β-transformed cells was confirmed. α-SMA is used as one of the defining markers of EMT, demonstrating the presence of an activated fibroblast or myofibroblast. However, other investigators have used fibroblast specific protein-1 (FSP-1) as a marker for EMT [104]. FSP-1, also known as S100-A4, has been used to demonstrate the presence of fibroblasts in UUO. However, questions about the specificity of FSP-1 remain, and may confound some of the findings in UUO.

• EMT is accompanied by loss of the epithelial antigen, E-cadherin. The effects of TGF-β are blocked by a neutralizing antibody to TGF-β. The loss of cell adhesion, expression of the mesenchymal markers, and subsequent degradation of the basement membrane allows for changes in shape and motility, which lead to migration into the interstitial space (Figure 7.11).

Several studies have examined EMT in UUO. Yang and Liu showed a marked decrease in E-cadherin and a marked increase in α- SMA in UUO [105]. There was also an increase in TGF-β receptors in renal tubules. When hepatocyte growth factor was administered, interstitial fibrosis was decreased, as well as the expression of α-SMA. Iwano *et al*. used a combination of bone marrow chimeras and transgenic reporter mice, and studied the expression of FSP+ cells in UUO [106]. They determined that a small population of FSP+ cells derived from bone marrow, but a larger proportion arose from local EMT of proximal tubular cells. Both FSP+ cell populations were able to synthesize collagen and to proliferate. Sato *et al*. have also demonstrated decreased E-cadherin and increased α-SMA expression in UUO [107]. Using Smad-3 knockouts (a downstream effector of TGF-β), they demonstrated that the decrease in E-cadherin and the increase in α-SMA can be reversed. Furthermore, Smad-3 knockouts exhibit less fibrosis

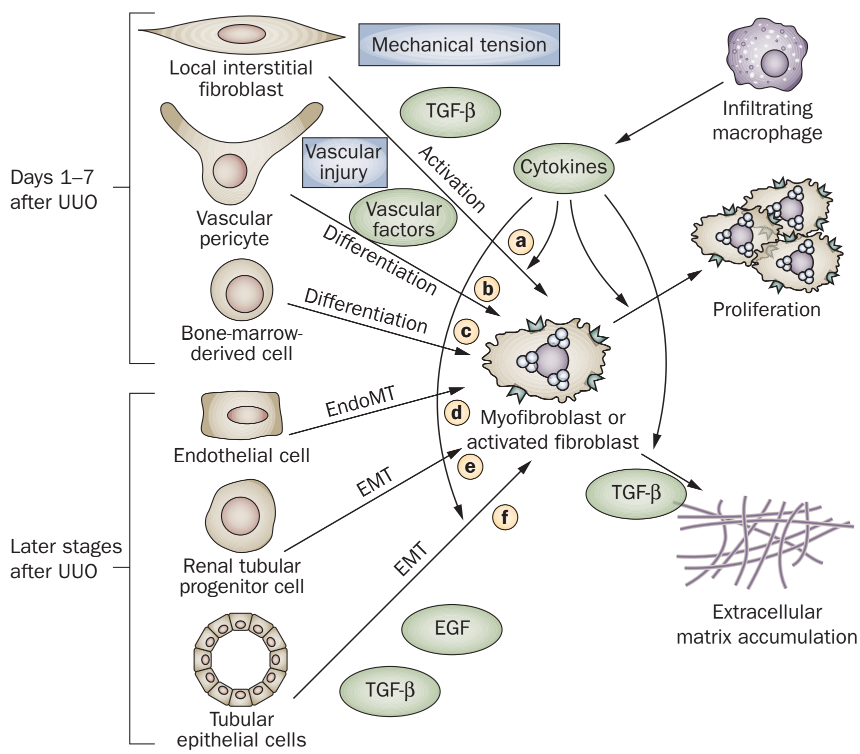

Figure 7.10 Origins of activated fibroblasts and myofibroblasts in the obstructed kidney. Local resident fibroblasts (a) are activated by mechanical stretch or cytokines such as transforming growth factor (TGF)-β. Myofibroblasts derive from differentiation of (b) vascular pericytes (as a result of vascular injury and release of vasoactive factors), (c) bone marrow derived cells, (d) endothelial cells [via endothelial–mesenchymal transition (EndoMT)], (e) renal tubular progenitor cells, and (f) tubular epithelial cells [via epithelial–mesenchymal transition (EMT), which is induced by various cytokines]. Myofibroblasts and activated fibroblasts proliferate and produce extracellular matrix. Infiltrating macrophages release cytokines that contribute to many of these processes. EGT, epidermal growth factor; UUO, unilateral ureteral obstruction (reproduced from Grande and Lopez-Novoa [100], with permission).

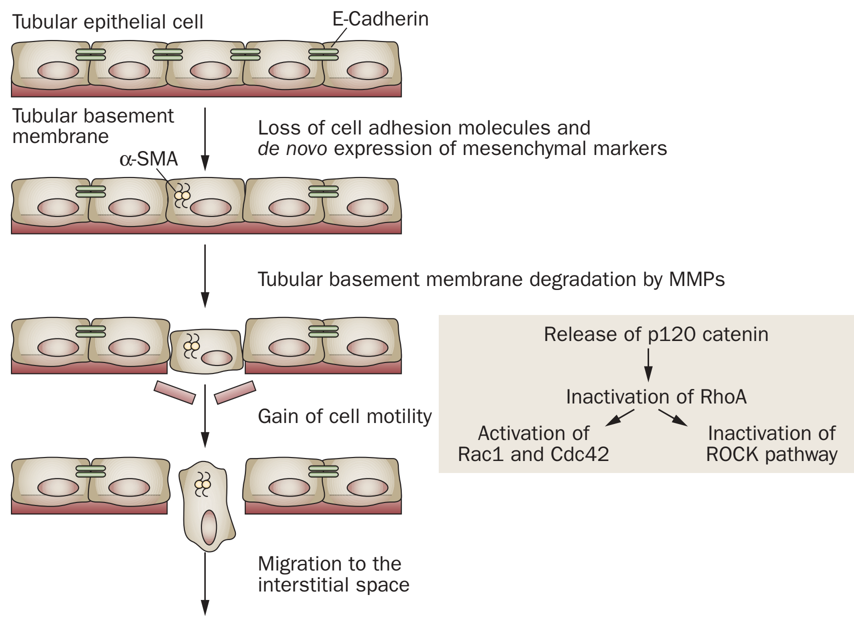

Figure 7.11 Stages of epithelial–mesenchymal transition (EMT). The initial steps of EMT – loss of cell adhesion (owing to downregulation of E-cadherin) and *de novo* expression of mesenchymal markers such as α-smooth muscle actin (SMA) – are followed by degradation of tubular basement membrane by selective matrix metalloproteinases (MMPs); finally, acquisition of motility (as a result of activation of small Rho GTPases) allows the cell to migrate from the tubular to the interstitial space. ROCK, Rho-associated coiled-coil forming protein kinase (reproduced from Grande and Lopez-Novoa [100], with permission).

than their wild-type counterparts. To examine the specific role of FSP-expressing fibroblasts in the fibrosis of UUO, Iwano *et al*. used methods to selectively remove the FSP+ cell population in the kidney. When these mice underwent UUO and kidneys were harvested 10 days later, both type I collagen deposition and fibrosis were reduced. This suggests that FSP+ fibroblasts are at least partially responsible for the fibrosis of UUO [106].

Endothelial cells

A new source of fibroblasts has recently been identified in cardiac fibrosis. Zeisberg *et al.* demonstrated that, similar to epithelial cells, TGF-β could induce endothelial cells to undergo transition to fibroblasts [108]. Treatment of mice in a model of pressure overload-induced fibrosis with BMP-7 reduced both endothelial cell transition to fibroblasts and the resulting cardiac fibrosis. Similarly in UUO, the same group found that 30–50% of fibroblasts coexpressed the endothelial cell marker CD-31. In addition, using transgenic mice and lineage tracing with TIE-2, the endothelial origin of a subset of fibroblasts in UUO was confirmed [109].

Bone marrow cells

Two different studies have demonstrated that bone marrow cells contribute to the population of fibroblasts in UUO. In the first, Iwano *et al*. demonstrated that a small number of bone marrow-derived cells are FSP+, but, as discussed above, a much larger number were derived from tubular epithelial cells [106]. In a more recent study, Roufosse *et al*. used transgenic mice in which production of collagen was accompanied by expression of luciferase reporter gene [110]. They clearly demonstrated fibrosis in the UUO model, but in chimeric mice in which bone marrow cells were labeled, no increase in reporter gene could be detected. Their conclusion was that intrinsic renal cells are responsible for collagen synthesis in UUO.

Renal progenitor cells

Cells identified as renal progenitor cells have been identified through BrdU staining. It has been shown that the BrdU-positive cells are among a population of cells which express vimentin, heat shock protein-47, and α-SMA [111]. The contribution of this population to fibrosis is unknown.

Pericytes

A population of pericytes has been shown to be the source of myofibroblasts in fibrosis in UUO. Pericytes are cells that line the vasculature; the smallest capillaries are partially covered by individual pericytes, whereas

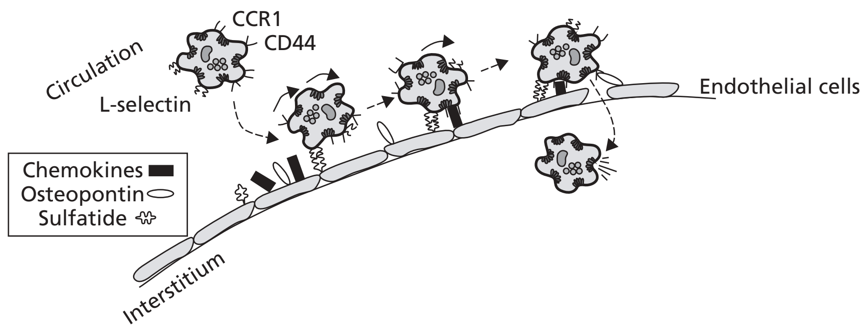

Figure 7.12 Hypothetic representation of cellular infiltration in unilateral ureteral obstruction (UUO) based on data obtained with knockout mice. UUO induces macrophage infiltration in the tubulointerstitium. In UUO, the interaction between L-selectin and sulfatide seems to mediate the initial contact (rolling) between macrophages and the vascular endothelium. These rolling macrophages are exposed to adhesion molecules like chemokines and osteopontin expressed on endothelial cells. The chemokines bind to chemokine receptors (in UUO mainly the CCR1) on the macrophages. Osteopontin binds to the CD44 receptor. This results in firm adhesion and transendothelial migration of macrophages. The role of other important molecules [including intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), and monocyte chemoattractant protein-1 (MCP-1)] involved in cellular infiltration shown to be induced in UUO has not been studied yet and should give a more complete picture of cellular infiltration in UUO (reproduced from Bascands and Schanstra [120], with permission).

intermediate size vessels are lined with cells whose properties are between pericytes and typical vascular smooth muscle cells [112]. Pericytes themselves have a phenotype which is between vascular smooth muscle cells and fibroblasts. Duffield *et al*. have published two studies in which they demonstrate that pericytes are the primary source of collagen-producing cells in UUO. In the first, transgenic mice in which green fluorescent protein (GFP) expression is under the regulation of the collagen 1α1 promoter, pericytes showed increased expression of GFP, indicating that collagen 1α1 was induced [113]. Furthermore, the pericytes detached and moved away from the capillaries. There is no unique marker for pericytes; however, both α-SMA and NG2 (high molecular weight melanoma associated antigen) have been used. In kidney, there was a marked increase in both NG2 and α-SMA in GFP-positive cells after UUO. In the more recent study, elegant fate-mapping studies were used to investigate the source of myofibroblasts in UUO [114]. The investigators demonstrated that *in vitro*, epithelial cells transform into myofibroblasts in the presence of TGF-β. However, the same cells labeled *in vivo*, either with red fluorescent protein or β-galactosidase, neither migrated past the tubular basement membrane nor contributed to the *in vivo* population of myofibroblasts.

Macrophage infiltration

There are very few macrophages in the normal kidney. Macrophages have also been localized in the obstructed kidney by morphologic examination [96]. Needleman *et al*. demonstrated that macrophages contributed to the exaggerated eicosanoid release in the isolated perfused rabbit kidney [115, 116]. Use of monoclonal antibodies has led to immunohistochemical identification of macrophages. Diamond *et al*. described an increase in macrophages in interstitial tissue by 12 h after UUO [117]. There was a continued increase through 96 h. Others have confirmed the presence of interstitial macrophages in UUO [88, 118, 119]. In a recent article by Bascands and Schanstra [120], the contribution of various adhesion molecules to the transendothelial migration of macrophages has been reviewed (Figure 7.12). Use of mice with knockout of specific adhesion molecules demonstrated that L-selectin and sulfatide mediate the initial contact between circulating macrophages and the underlying vascular endothelium. The CCR1 receptor on macrophages is a site for binding adhesion molecules like osteopontin, which can then effect adhesion of macrophages to the endothelium. Furthermore, using either CCR1 or osteopontin knockout mice, researchers have been able to demonstrate decreased fibrosis in the UUO model [121, 122].

TGF-β

Macrophages, fibroblasts, and tubular cells in the obstructed kidney produce a wide variety of cytokines which contribute to the fibrosis of obstruction. Foremost among these mediators is TGF-β, whose role in EMT was described above. Increased mRNA expression of TGF-β was found as early as 10 h after obstruction and was increased through 96 h [117, 123]. When tubules and glomeruli from the obstructed kidney were separated, glomerular TGF-β mRNA was found not to differ from controls, whereas tubular TGF-β mRNA was increased in UUO [124]. TGF-β localization in obstructed kidneys

has been studied using immunohistochemistry, and conflicting results have been found. Wright *et al.* found that tubular TGF-β was increased in the obstructed rat kidney medulla; cortical TGF-β was not greatly affected by UUO [88]. This was confirmed by the measurement of tissue levels of TGF-β, which were found to be increased in the medulla after UUO. TGF-β has been found in association with interstitial macrophages in early obstruction and not in association with tubules [117]. TGF-β has also been found in interstitial cells, which have not been characterized, but may be either macrophages or fibroblasts. Kaneto *et al.* examined renal samples from nine patients who underwent nephroureterectomy because of transitional carcinoma of the ureter [125]. All patients exhibited hydronephrosis by either ultrasound or IVU. Control renal tissue was obtained from presumed normal sections of kidneys of patients with renal tumors. Compared to control tissue, kidneys from patients with hydronephrosis exhibited increased interstitial volume and collagen deposition. Immunoreactive TGF-β was detected in the interstitium, but not in the tubules, and was increased in obstructed kidneys.

Strategies to decrease fibrosis

Over the last 25 years, investigators have attempted to decrease the fibrosis of UUO through either drug treatments or genetic manipulation. Many of these have targeted either TGF-β or angiotensin II, both of which have been found to be profibrotic in UUO (for reviews see [1, 2]). In studies in our laboratories, rats underwent UUO and were given either control monoclonal antibody, 1D11 or enalapril (Angiotensin converting enzyme inhibitor), or 1D11/enalapril combination, for 14 days. Kidneys were harvested and examined for fibrosis and FSP-1 expression, apoptosis, macrophage infiltration, and TGF-ß expression. UUO was found to induce fibrosis, apoptosis, macrophage infiltration, and TGF-ß expression in the obstructed kidney. Administration of either 1D11 or enalapril individually significantly decreased all these changes; when 1D11 and enalapril were combined, there was little additive effect, and the combination did not provide full protection against damage [126]. The results demonstrate that, for the most part, combination therapy is not additive in UUO. This could be due the continued presence of a physical obstruction or to biochemical differences between UUO and other renal disease models. Furthermore, it suggests that other targets may be amenable to pharmacologic manipulation in UUO.

Proliferation and apoptosis

Recovery from tissue injury involves both proliferation and apoptosis of resident and infiltrating cell populations. With coordination of these processes, the tissue can recover. When apoptosis and/or proliferation are dysregulated, tissue fibrosis ensues. Truong *et al.* provided the first detailed analysis of both apoptosis and proliferation in UUO [127]. They studied the tubular, interstitial, and macrophage components from 0 to 90 days of UUO. There was virtually no change in glomerular apoptosis or proliferation throughout the period examined. Tubular proliferation peaked at day 10, whereas interstitial proliferation exhibited two peaks: a broad peak at days 10–20, and a sharper peak at day 75. The rate of proliferation of tubule cells was 10-fold higher than that of interstitial cells. There was a sharp peak in tubular apoptosis at day 25, whereas interstitial apoptosis peaked at day 75. The apoptotic rate was twofold higher in tubular cells than in interstitial cells. Choi *et al.* demonstrated similar findings in mice studied from 4 to 45 days of UUO [128]. Tubular apoptosis was maximal at day 15, whereas interstitial apoptosis was still increasing at day 45.

Chevalier *et al.* examined apoptosis and proliferation in adult rats with 3-day UUO [1]. There was an increase in apoptosis and proliferation in both tubular and interstitial compartments, which was not affected by blockade of either the AT1 or AT2 receptor. Miyajima *et al*. studied apoptosis and proliferation in iNOS knockout mice [129]. They showed that iNOS knockout mice exhibited more tubular apoptosis and more proliferation than wild-type controls. In contrast, when rats were treated with 1D11, a TGF-β antibody, tubular apoptosis was markedly decreased, whereas tubular proliferation was increased [130]. Chevalier *et al.* also studied expression of bcl-2 and bax, antiapoptotic and proapoptotic proteins, respectively [131]. Sham-operated kidney showed diffuse tubular bcl-2 and bax staining. In 14-day UUO, bcl-2 was increased in scattered nonapoptotic tubules, with minimal staining in apoptotic dilated tubules. Bax staining overlaps bcl-2. In contrast, Miyajima *et al*. found virtually no expression of bcl-2 in sham-operated or obstructed kidneys [130]. However, in the presence of 1D11, and markedly decreased levels of renal TGF-β, there was expression of bcl-2 in obstructed kidneys.

Docherty *et al*. suggest that tubular apoptosis is a major contributor to fibrosis in UUO, and conversely that inhibiting apoptosis decreases fibrosis in UUO [132]. Thus, they review the evidence that tubular apoptosis in UUO can result from several factor associated with the response to UUO, including stretch, hypoxia, and oxidative stress. The apoptosis caused by these factors then produces an inflammatory response, resulting in the synthesis and deposition of extracellular matrix (Figure 7.13. Thus, the function of several known antifibrotic agents can be explained by effects on apoptosis. We have recently used a tetrapeptide antioxidant,

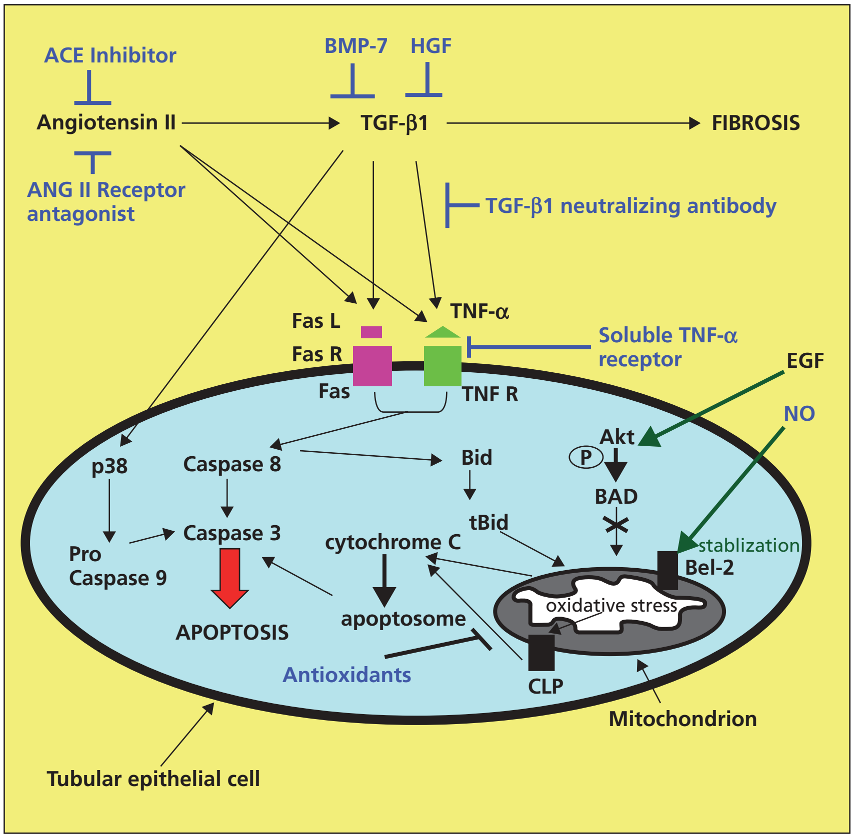

Figure 7.13 Summary of mediators and mechanisms shown to block tubular cell apoptosis following unilateral ureteral obstruction (UUO). Figure details the likely mechanisms of action of antiapoptotic strategies utilized in the inhibition of tubular cell apoptosis in animal models of UUO. Blunt ended blue lines and green arrow-tipped lines indicate the site/stage of antiapoptotic effect. [132], with permission).

which concentrates in the inner mitochondrial membrane to prevent cellular apoptosis, in the UUO model. We were able to demonstrate decreased apoptosis and fibrosis, along with decreased oxidative stress in the UUO kidney [133]. Most of the strategies which target tubular apoptosis also have effects on epithelial–mesenchymal transdifferentiation, and it may be difficult to separate these two different pathways. With the new description of other cell types and other cell transdifferentiations, as well as mediators such as cytokines or reactive oxygen species, there may be new targets which can be developed to improve antifibrotic therapy.

CHAPTER 8
Special Anesthetic Considerations for Endourology: Ureteroscopy and Percutaneous Nephrolithotomy

Sarah G. Bodin & Angela F. Edwards
Department of Anesthesiology, Wake Forest University Health Sciences, Winston-Salem, NC, USA

Endourology presents unique challenges for providing anesthesia that allows for safe care, optimum surgical conditions, and a low side effect profile. Patients with nephrolithiasis frequently present with comorbidities linked to the "metabolic syndrome" (hypertension, elevated body mass index, diabetes or insulin resistance) that should be considered carefully when planning an anesthetic [1]. Further, spinal cord injury patients have a higher incidence of nephrolithiasis, due to chronic infections, immobility, and metabolic conditions, as do other chronically immobile patients. These patients pose specific challenges to providing safe anesthesia. The faster recovery afforded by minimally invasive techniques, compared to conventional open techniques, opens a wider patient population to candidacy, such as those with severe cardiac or pulmonary comorbidities who might not have been considered for conventional approaches.

Many types of anesthesia have been used successfully for ureteroscopic and percutaneous techniques for renal stone extraction, including general, subarachnoid block (spinal), epidural, and sedation with local anesthetic supplementation [2–4]. This chapter will address procedure-specific risks and requirements, physiologic changes from intraoperative surgical and anesthetic stresses, the assessment of patient-specific risks, and postoperative recovery from the anesthetic. All of these issues should influence the choice and planning of the anesthetic for an individual patient. Lastly, the strengths and preferences of the surgeons and anesthesiologists will influence anesthetic technique. Communication between these parties and the patient should occur prior to the day of surgery in order to choose an optimal anesthetic technique.

Procedural considerations for endourology

Fluid absorption during endourologic procedures can be significant during transurethral resection of the prostate (TURP), but is less of an issue during more minor ureteroscopic procedures. A study quantitating fluid absorption in 23 patients undergoing ureteroscopy (either semi-rigid or flexible scopes), using normal saline irrigation at a maximum infusion pressure of 200 mmHg, demonstrated mean fluid absorption of 54 mL (maximum 137 mL). In this study, the mean total irrigation used was 2531 mL (maximum 5580 mL) [5]. Moreover, another study looking at the amount of fluid absorbed during percutaneous nephrolithotomy in 148 patients, where all patients received 0.9% saline as irrigant, revealed maximum absorption of 474 mL. Factors suggested to increase irrigant absorption included use of a primary percutaneous access tract, elevated blood loss, high amounts of irrigating fluid, and significant perforation of the pelvicalaceal wall. This study failed to demonstrate any intra- or post-operative electrolyte imbalances [6]. Furthermore, during procedures involving continuous bladder irrigation, urine output is often difficult for the anesthesiologist to quantitate. This aspect emphasizes the importance of communication between surgeon and anesthesiologist, in that the surgeon may be able to estimate urine output while visualizing the surgical field.

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Both percutaneous nephrolithotomy (PCNL) and ureteroscopy involve irrigation fluids at room temperature, which removes heat from the patient. This, in combination with the known redistributive effect of general anesthesia (GA), which alters patient heat distribution, potentiates the risk of hypothermia. The redistribution of heat from the patient's core to the periphery, and subsequent heat loss to radiation, conduction, convection, and evaporation put the patient at risk. GA interferes with the body's ability to maintain its thermal set-point through hypothalamic dysfunction. Even mild hypothermia is known to contribute to an increase in perioperative cardiac ischemic events (by threefold), surgical wound infections (by threefold), decreased metabolism of drugs, increased bleeding and transfusion requirement, and increased length of stay [7]. Diligent attention to patient warming during and after induction of anesthesia, through forced air warming, maintenance of the room temperature, warming intravenous fluids and blood products, is essential to avoid hypothermia. This is especially true when large irrigation volumes are to be administered.

Patients with urinary infections or evolving urosepsis associated with obstructing ureteral stones may be febrile, relatively hypovolemic, and hyperdynamic, requiring careful anesthetic management. Fever increases metabolic rate, fluid requirements, and rate of metabolism of certain drugs. This presents complications with anesthetic management that will be covered below.

Lastly, renal stones positioned higher in the ureter, upper kidney poles, and staghorn calculi all increase the complexity of maneuvers required for removal, possibly increasing the duration of surgery and depth of anesthesia required. Similarly, position and size of ureteral tumors approached endoscopically may dictate length of procedure and depth of anesthetic required.

Ureteroscopy: procedural risks and anesthetic consideration

Fortunately, since modern ureteroscopy does not invade the peritoneum and avoids major blood or fluid loss requiring significant volume resuscitation, as well as serious hemodynamic challenges from catecholamine release, the procedure itself poses a low risk of cardiac complications. (<1%) [8]. As a lower abdominal procedure, without significant inherent postoperative pain or pulmonary dysfunction, individual patient risk factors take greater importance, and will be the focus of a later section of this chapter.

Many types of anesthesia for ureteroscopy have been described; from GA to regional and local, either with or without sedation, and all have been used successfully. Many surgeons advocate the use of GA with muscle relaxation (including endotracheal intubation) for most ureteroscopic stone manipulations. This preference reflects concern about safely accessing the kidney and ureters during spontaneous respiration or other voluntary or involuntary patient movement [9]. GA facilitates a quiescent surgical field as ventilation can be briefly held, to permit focus of the YAG (yttrium–aluminum–garnet) laser on the stone, minimizing risk of inadvertent injury to the urethra, bladder, and pelvic vessels. Lastly, in patients undergoing semi-rigid ureteroscopy, a GA provides better analgesia to facilitate better patient tolerance of a larger ureteroscope.

Muscle relaxation may be more important when accessing mid-to-upper urethral stones than lower. Even when the stone is in the lower ureter, it may migrate higher during manipulation with irrigation pressure and instrumentation. This circumstance makes a higher level of anesthesia and neuromuscular blockade (NMB) desirable, to avoid the possibility of ureteral tears or avulsion, or other retroperitoneal injury. However, multiple studies have demonstrated the safety and efficacy of both local anesthesia and spinal anesthesia for ureteroscopic procedures [2, 10, 11]. If rigid equipment of larger caliber is needed, then more substantial intraoperative analgesia and anesthesia will be required. If using more modern, small diameter flexible scopes, local anesthesia and sedation may be more successfully employed and tolerated. In a recent review of the literature, it was noted that in select [American Society of Anesthesiologists (ASA) physical status I and II] patients, the incidence of ureteral trauma is minimal whether utilizing GA, subarachnoid block, or local with monitored anesthesia care (MAC) for the procedure [2, 12–14].

Other factors which may influence the depth of anesthesia and analgesia necessary are patient gender and complexity of the planned procedure (larger, more complex stone burden, location, or more complex tumor for resection). Patients in whom a procedure of long duration is expected may tolerate GA or regional anesthesia better. Women tend to tolerate local anesthesia somewhat better than men, perhaps due to better tolerance of instruments through the shorter membranous urethra and bladder neck [10]. The use of higher distending pressures within the ureter also predicts higher discomfort levels and makes toleration of lighter anesthesia more difficult. Several factors that may dictate ureteroscopic treatment of renal calculi rather than extracorporeal shock-wave lithotripsy (ESWL) or PCNL, e.g. super morbid obesity, acute infection, and coagulation abnormalities, also complicate provision of safe anesthesia. These factors must also be considered carefully when planning the anesthetic [9].

Lastly, positioning the patient for ureteroscopy deserves brief mention. Fortunately, the usual lithotomy position with the patient's head near the anesthesia

team makes airway management and maintenance of anesthesia straightforward. The lithotomy position increases venous return from the lower extremities, which is well-tolerated by most patients. Warner *et al*. found that the overall duration of lithotomy, greater than 2 h in 991 patients while under GA, increased the risk of lower extremity sensory neuropathies significantly, compared to procedures of shorter duration [15]. This emphasizes the need for shorter duration of procedures and optimal hemodynamic management during these procedures.

Percutaneous nephrolithotomy: patient risks and anesthetic considerations

The risks associated with this procedure are more significant due to the increased invasiveness, prone positioning, surgical stress response elicited, and potential blood loss relative to ureteroscopic procedures. However, PCNL has been performed safely and with low morbidity in many patients, including those of ASA III or IV, as well as the morbidly obese [16]. The procedure is considered “intermediate” in cardiac risk [1–5 % incidence of cardiac death or myocardial infarction (MI)] according to the 2007 American College of Cardiology (ACC)/ American Heart Association (AHA) Guidelines (Table 8.1), due to the risks associated with the procedure itself.

As with ureteroscopy, all types of anesthesia have been used successfully for PCNL procedures. This includes general, neuraxial, and local with sedation during access, tract dilation, and stone manipulation in the same setting. This is well-described in the literature [3, 4, 17]. In our institution, GA is most frequently used due to the anticipated duration and complexity of the procedure, as well as surgeon preference. Patient positioning, complexity of procedure, and patient comorbidities are all factors to be considered when planning the anesthetic for PCNL. Interestingly, one randomized controlled trial demonstrated improved patient satisfaction, shorter postanesthesia care unit (PACU) times, and less postoperative pain through postoperative day 2, in 180 patients undergoing PCNL via combined spinal–epidural anesthesia versus GA [3].

With regards to positioning, the prone oblique position is more frequently utilized for PCNL. However, the supine oblique position has also been employed to facilitate access to the surgical site [18]. Prone positioning increases the complexity of the anesthetic somewhat. Airway maintenance, adequate ventilation, and avoidance of cervical spine and pressure point injuries require more proactive maneuvers, especially in the obese and morbidly obese. Bagrodia *et al.* confirmed that obesity had no impact on cost, length of stay, and complication and stone-free rates compared to normal weight patients [19].

Table 8.1 Cardiac risk* stratification for noncardiac surgical procedures (reproduced from *Circulation* 2007;116:1971–1996, ©2007 American Heart Association, Inc., with permission).

*Combined incidence of cardiac death and nonfatal myocardial infarction.
†These procedures do not generally require further preoperative cardiac testing.

Airway maintenance:

Prone positioning requires that the patient’s face be maintained free of pressure on prominences (eyes, nose, ears, cheekbones), with appropriate cushioning and support. Several commercial foam face cushions and support systems are available. The cervical spine must be maintained in a neutral position. The endotracheal tube must be taped securely at an appropriate depth and positioned free of kinks or pressure so that there is not obstruction within the airway during patient repositioning or during the procedure. A bite block should be placed between upper and lower molars (or gums if patient is edentulous) to prevent patient biting on the tongue, soft tissues, or endotracheal tube. The trachea must be positioned without pressure or risk of impeding a patent airway. One useful commercial device that serves all these purposes is the ProneView® Protective Helmet system (Dupaco, UK). This device is used for head and face positioning and incorporates a padded cradle, supported by short posts, with a mirror underneath to allow easy visualization of the patient’s face and endotracheal tube (Figure 8.1).

Positioning

During the time in which the patient is turned prone and positioned for surgery, the anesthesia team must remain hypervigilant about the patient’s physiologic and anesthetic status. Monitoring devices may be removed tem-

Figure 8.1 ProneView® protective helmet system (Dupaco, UK).

porarily while turning to avoid entanglement. These monitors must be quickly replaced, however, to monitor changes that can occur during repositioning. With such changes in position, the ability to ventilate the patient's lungs, maintain intravascular volume distribution (changes in venous return), cardiac output, as well as adequate anesthesia levels relative to variable levels of stimulation, can present quite a challenge. For a healthy, adequately anesthetized patient, these may be clinically inconsequential; however, for those with marginal cardiovascular or pulmonary reserve, it can be a more dangerous time. The anesthesia team must ensure the airway is maintained while repositioning, without dislodging the endotracheal tube, and maintain cervical spine neutrality. Although cervical spine injury during prone positioning under anesthesia is rare, it has been reported with both overflexion and overextension during prolonged procedures [20]. At greatest risk are patients with known or presumed cervical spine pathology, including Down's syndrome or rheumatoid arthritis, or patients with myelopathic symptoms. Furthermore, protruding facial features must be positioned and maintained free of compression (ears, nose, lips), and the eyes and orbital contents especially must avoid direct pressure damage. This, fortunately, appears to be rarely reported in the literature but remains a concern. Lastly, postoperative visual loss (POVL) is a dreaded yet infrequent complication of prone spine surgery (0.2% of spinal surgeries in one review [21]). However, prone positioning itself has not been identified as an independent risk factor for POVL [20].

The chest must be elevated on rolls to protect intra-abdominal contents from pressure, and to facilitate positive pressure ventilation by allowing full diaphragmatic excursion and full lung expansion. Elevated intra-abdominal pressure may impede effective mechanical ventilation and oxygenation if this does not occur. Improper positioning of chest rolls and lower extremities may result in hemodynamic changes from compression of the inferior vena cava and iliac veins, thereby decreasing preload and cardiac output.

The shoulders should be supported without significant forward rotation so as to protect both the brachial plexus from excessive shear force and optimize perfusion to the upper extremities. Breasts in women and external genitalia in men must be checked such that they are free of compression. Arms can be tucked and padded at the sides, or, more frequently, as with our institution, raised above the head with both shoulders and elbows positioned at 90°. Of course, this presumes that the patient has no restrictions to range of motion or risk of shoulder dislocation. Such positioning allows access to the arms in case further peripheral intravenous access is needed intraoperatively. The patient's knees and feet should be protected with padding and slightly flexed such that there is little or no contact with the operative bed. Fortunately, there is as yet no convincing evidence in the literature that the incidence of peripheral nerve injury is increased during prone positioning [20].

If the procedure can be performed under local anesthesia with sedation, positioning can be achieved with the patient's assistance prior to heavy sedation, to ensure comfort and adequate padding. If it is performed under epidural or spinal anesthesia with a local anesthetic that induces a motor block, the patient may need to be moved by the surgical team, but will be able to position the head and upper body, prior to sedation being initiated. Further, some neuraxial blocks may allow delayed onset of the motor block, which gives the patient time for lower body positioning.

Access to the middle and lower poles of the kidneys is usually achieved subcostally. But occasionally access to the upper calyx is necessary to reach the ureteropelvic junction, proximal ureter, or to improve exposure to calyx and renal pelvis through a supracostal approach. The supracostal approach to the upper pole of the kidney can encroach upon the pleura, so the anesthesiologist and surgeon should communicate frequently during access and tract dilation to monitor for pleural injury, such as hydro- or pneumo-thorax [22]. If supracostal access is necessary, lateral access (at the lateral end of the 12th or 11th rib) during the end-exhalation phase of the respiratory cycle may minimize the chance of pleural and pulmonary injury [22]. Although most surgeons and anesthesiologists prefer GA to control ventilation partly for this reason, safe, successful spinal anesthesia for PCNL (including for supracostal access) has been described [23].

Physiologic changes during prone positioning

A number of physiologic changes to anesthetized patients occur in the prone position. Of benefit is the

more uniform distribution of pulmonary blood flow, improving ventilation to perfusion matching and oxygenation [20, 24]. Also, functional residual capacity increases (compared to the anesthetized supine position) in normal weight and less so in obese patients [20]. Care must be taken to position chest rolls so that abdominal contents and the chest wall can move freely, or mechanical obstruction to ventilation may occur, increasing peak airway pressures and inhibiting effective mechanical ventilation. Direct pressure to the abdominal contents may also be injurious, causing decreases in visceral perfusion. Such mechanical compression has been reported to cause ischemia.

Patient mean arterial pressure (MAP) often decreases in the prone position. This has been thought to be due to decreases in cardiac index (CI) and stroke volume [20, 25]. Though the complete reasons for this are unclear, main theories are that this position impedes venous return and/or impedes left ventricular outflow during systole as a result of increased intrathoracic pressure. In either case, the decrease in CI is usually well-tolerated in healthy individuals with good cardiac reserve, due to reflexive increases in systemic vascular resistance and MAP. However, in those with poor cardiovascular reserve, vasopressor support may be indicated to maintain perfusion pressure. Augmentation of preload must be undertaken carefully in those who may be at risk of volume overload (with congestive heart failure, diastolic dysfunction, or renal failure). The decrease in CI underscores the importance of careful positioning to ensure minimal effect on venous return, leaving the abdominal contents and thorax freely mobile.

Complexity of surgical procedure: considerations for the anesthetic

With a larger more complicated stone burden that requires a prolonged surgical time, the likelihood of needing general or neuraxial (spinal or epidural) anesthesia increases. For cases involving access, dilation, and stone extraction during the same procedure, a “type and screen” for blood products should be considered in the event of unanticipated significant blood loss. Further, adequate intravenous access should be secured prior to initiation of surgery. Utilizing the “type and cross” method of reserving blood products can lead to extra cost, blood wastage, and transfusing red cells of increased age that have diminished oxygen carrying capacity. The time for most blood banks to convert a “type and screen” to available crossed units is minimal unless the patient has been recently transfused or has rare antibodies. Many centers have described a “maximum surgical blood ordering schedule” to minimize these issues [26].

Longer PCNL procedures may lead to significant dependent edema to inferiorly located anatomy. Swelling of the face and laryngeal structures are of greatest concern. These areas should be evaluated carefully prior to extubation. If there is concern regarding supraglottic airway edema, extubation should be delayed until the edema has resolved significantly. This may be evaluated by an endotracheal tube “leak check” to ensure sufficient ventilation exchange around the endotracheal tube with cuff deflated. In most patients, a brief period of head elevation during recovery is sufficient to resolve facial edema and permit extubation.

Preoperative assessment for ureteroscopy and percutaneous nephrolithotomy

The preoperative assessment of patients prior to ureteroscopy and PCNL is similar to that prior to most surgical procedures, except for these lower-risk procedures there is minimal blood loss, fluid loss, or hemodynamic shifts. The fundamental purpose of preoperative evaluation is to obtain pertinent information regarding the patient’s current and past medical history (*diagnosis*), to evaluate the patient’s intraoperative risk (*risk assessment*), and to consider interventions to minimize patient risk (*optimization*) [27, 28]. The overriding goal is to reduce patient morbidity and risk related to the invasiveness of surgery and the patient’s coexisting diseases while promoting perioperative efficiency and reducing length of stay (*perioperative planning*) [27]. The Joint Commission requires that all surgical patients receive a preoperative anesthetic evaluation, and the ASA has established basic standards of preanesthetic care with the goals of assessing and modifying patient comorbidities to improve outcome [27]. The preoperative evaluation is an opportunity to educate and prepare the patient physiologically and psychologically for the upcoming procedure. While it is helpful to have data and risk stratification comments from referring and consulting physicians, notes that state “cleared for surgery” are of little use or benefit to the anesthesiologist preparing for intraoperative management [8, 29].

Inherent to the preoperative assessment is a detailed history and targeted physical examination to identify physiologic changes associated with certain disease states. Evaluating the demographics of age, height, weight, and vital signs, to a full list of medications, allergies, and prior medical, surgical, and social factors is necessary. Review of prior anesthetic records is essential to detect the presence of a difficult airway, latex or drug allergy, history of malignant hyperthermia, autonomic hyperreflexia following spinal cord injury, and the individual’s response to surgical stress and specific anesthetics. Furthermore, knowledge of previous laboratory values and ancillary studies facilitates anesthetic plan-

ning. If prior labs are unavailable, goal-directed, diagnosis based testing may be appropriate to further elucidate the severity of certain disease states [30–33]. Diagnosis-based preoperative testing may identify a need for change in the patient's perioperative management [32, 34, 35]. Conversely, widespread preoperative testing without consideration of actual utility, cost, or effect on management is not beneficial ("screening" tests), and may actually increase physician liability [31]. Testing should be based upon positive physical examination findings and anticipated physiologic disturbances, such as irrigant absorption or blood loss. Results should aid in assessing the degree of medical optimization and in anesthetic planning.

The preanesthetic medical history should include a complete list of medications, including over the counter and homeopathic herbal agents, in order to define an appropriate preoperative medication regimen and anticipate potential interactions with anesthetic agents. Evaluating the patient's medications and making recommendations prior to surgery serves to minimize potential drug interactions, complications, and cancellations on the day of surgery. Instructions given to the patient both the day before and on the morning of surgery depend upon the patient's comorbidities and the rationale for treatment [36–40]. Examples of some commonly withheld medications prior to surgery are listed in Tables 8.2 and 8.3.

The medication list can also provide clues as to the severity of the patient's underlying disease states. For example, a patient with significant congestive heart failure may be taking diuretics, digoxin, angiotensin II inhibitors [angiotensin II blockers (ARBs) or angiotensin converting enzyme (ACE) inhibitors], beta-blockers, and/or calcium channel blockers. Changes in this regimen could significantly alter the patient's fluid balance, myocardial function, and tolerance of both induction and maintenance of anesthesia. Patients with intracoronary stents, either drug-eluting or bare metal, are typically taking a combination of antiplatelet agents (clopidogrel, ticlopidine, and/or Aspirin) that if discontinued prematurely increase the risk of acute stent thrombosis and MI [38]. These medications should be carefully adjusted in accordance with the ACC/AHA guidelines for management to avoid life threatening acute coronary syndrome and sudden death [36]. Furthermore, certain medications, including most antihypertensives, beta-blockers, H_2 blockers, and proton pump inhibitors should be continued through the morning of surgery. Clonidine, an alpha-agonist, should be continued through surgery to avoid extreme rebound hypertension. Exceptions to the continuation of antihypertensive agents may include ARBs and ACE inhibitors, as they potentiate hypotension common during induction of anesthesia [41, 42]. Continuing beta-blocking agents, statins, and Aspirin for patients with known coronary artery disease or prior MI is paramount for myocardial protection during the perioperative period [36, 39, 40]. This combination of agents has been suggested to maintain balanced coronary blood flow during times of stress and hemodynamic instability [28, 43]. The pleiomorphic (arterial plaque stabilizing) effects of statins may provide this myocardial protection [39, 44].

Table 8.2 Medications commonly discontinued several days prior to surgery.

Medication	Special considerations/comments
Tricyclic antidepressants	Continue for severe depression
Monoamine oxidase inhibitors (MAOIs)	Continue for severe condition (use MAOI – safe anesthetic agents, avoid meperidine)
Metformin	Hold 48 h prior to surgery; risk of lactic acidosis
Oral hypoglycemic agents	Hold the morning of surgery
Herbal therapy (fish oil, ginseng, ginkgo biloba, etc.)	Potential multisystem (anticoagulant, cardiovascular effects)
Warfarin (Comadin)	Stop 3–5 days prior to surgery; if high risk of thromboembolism, bridge with heparin or low molecular weight heparin (LMWH)
Clopidogrel (Plavix), cilostazol (Pletal), dipyridamole (persantine)	Hold for 5–7 days unless antiplatelet, antithrombotic therapy required for secondary prophylaxis (and low risk of surgical bleeding)
	Duration of effect: cilostazol and dipyridamole < clopidogrel, Aspirin, ticlidopine
Nonsteroidal anti-inflammatory drugs (NSAIDs)	Hold for renal insufficiency

None of these recommendations is absolute; decisions made on an individual basis.

Table 8.3 Medications commonly withheld on the morning of surgery.

Medication	Special consideration/comments
Angiotensin converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs)	Continue with severe congestive heart failure (CHF), valvular insufficiency, refractory hypertension; otherwise hold to avoid severe hypotension during induction
Diuretics	Continue for severe CHF (esp. if twice daily dosing)
Phospohdiesterase-5 inhibitors	Hold to avoid severe hypotension (except in cases of severe pulmonary hypertension)
Lithium	Interactions with anesthetic agents
Disulfiram (Antabuse)	Affects metabolism of warfarin, phenytoin, etc.
Alendronate sodium (Fosamax)	Transient esophageal irritation
Particulate antacids	Risks pneumonitis with aspiration
Long acting insulin (e.g. NPH, glargine)	Continue the evening before surgery; glargine (Lantus) continue as usual the day of surgery, check glucose morning of surgery
Oral hypoglycemics	Hold the day of surgery
Pyridostigmine (e.g. in myasthenia gravis)	May interfere with neuromuscular blocking agents; continue as usual if risk of severe weakness or dysphasia (craniobulbar symptoms),
Prednisone, chronic immunosuppressive agents	Continue post transplant antirejection regimen, continue antiretroviral agents (HIV)
Low molecular weight heparin (Enoxaparin)	May replace with warfarin; typically hold for 12–24 h depending upon anticipated neuraxial blockade (see Table 8.7, ASRA Guidelines)

Patients with diabetes mellitus pose challenges with the timing of surgical procedures and maintenance of euglycemia. Ideally, insulin dependent diabetics should be scheduled early on the morning of surgery and maintained on exogenous insulin serving basal requirements (glargine, subcutaneous insulin pumps, etc.). Noninsulin dependent diabetics can withhold most medications on the day of surgery. In general, when planning preoperative medication adjustments, careful consideration must be given to both the invasiveness of the anticipated procedure and the surgical stress response, as well as the patient's degree of medical management, functional status, and tolerance of potential hemodynamic shifts [45, 46].

Additionally, certain disease states are of great significance when planning anesthetic management. These need to be identified as the patient's perioperative course and anesthetic management could be significantly altered by derangements in either medical management or physical symptoms. Known predictors of increased perioperative cardiovascular risk include unstable coronary syndromes, recent MI (<30 days), unstable angina, and poorly compensated congestive heart failure [8, 37]. Patients with significant arrhythmias (high-grade atrioventricular block, symptomatic arrhythmias with underlying heart disease, or supraventricular arrhythmias with uncontrolled ventricular rate and severe valvular disease) have increased risk of complications during noncardiac procedures (>5%). Patients presenting with these clinical predictors of cardiovascular disease warrant further evaluation prior to elective procedures, including low-risk procedures. This may involve reviewing an electrocardiogram (ECG), transthoracic echocardiography, or cardiac catheterization to determine ventricular function by a cardiologist to determine myocardial reserve. Intermediate risk factors, such as mild angina pectoris, prior MI (>30 days) by history or pathologic Q waves, compensated congestive heart failure, diabetes mellitus, and renal insufficiency, pose challenges for management but fewer risks to the patient in the immediate perioperative period, especially during lower risk procedures. These issues may be stable and medically managed and may not warrant further evaluation [8].

Assessing pulmonary function requires a basic physical examination and screening assessment that includes questions regarding the history of tobacco use dyspnea, cough, wheezing, stridor, snoring, sleep apnea, or symptoms of recent upper respiratory tract infection [47]. Physical examination should assess diminished breath sounds, wheezing, stridor, or rales, as well as respiratory rate, chest excursion, and use of accessory muscles of respiration. The degree of baseline dyspnea should be assessed relative to physical exertion or exercise tolerance. Further tests (spirometry, lung volumes, and/or arterial blood gas) may be useful to anticipate challenges

with anesthesia [48, 49]. Patients with diminished pulmonary reserve from longstanding obstructive or restrictive lung disease, neurodegenerative disorders, or paralysis may not tolerate the muscle relaxation associated with GA, sedation, or neuraxial blockade (spinal or epidural). Such patients may be dependent upon accessory muscles of respiration to maintain adequate ventilation and thus may be prone to needing prolonged intubation and ventilatory support [49, 50].

All of these medical issues must be weighed relative to the risk of surgical procedure, surgical stress response, and potential for hemodynamic fluctuations. Because ureteroscopy and PCNL are considered relatively low risk procedures, even moderate to intermediate patient risk factors pose less overall risk of postoperative morbidity [51]. Such is the case for minor cardiovascular risk factors, including advanced age, abnormal ECG (left ventricular hypertrophy, left bundle branch block, ST-T abnormalities), low functional capacity, history of stroke, or systemic hypertension [8]. It is worth noting that *functional capacity or exercise tolerance* is another important determinant of patient status that translates to perioperative risk [8]. This unique indicator provides valuable information regarding the patient's overall health status and physical robustness. An excellent exercise tolerance [>8–10 metabolic equivalents of task (METS)], even in patients with stable angina, suggests that the patient can generate a cardiac output adequate to meet metabolic demands during surgery. Conversely, patients who experience severe dyspnea or chest pain during minimal exertion (<1–3 METS) may have extensive coronary artery disease and greater risk. Self-reported estimate of exercise tolerance in metabolic equivalents or perceived level of daily exertion has been shown to correlate with perioperative complications [52]. Reilly *et al*. evaluated the predictive value of self-reported exercise tolerance for serious postoperative complications. They demonstrated that limits in preoperative functional capacity, as defined by an inability to walk four blocks or climb two flights of stairs, independently predicted complications with an odds ratio of 1.94 [53]. This study and others further support the lack of benefit of further testing if a patient reports good exercise tolerance, independent of surgical severity, complexity, or anticipated method of anesthesia [53].

With the information detailed in the preoperative assessment, the anesthesiologist planning the anesthetic for the procedure should be adequately prepared to design an anesthetic that minimizes postoperative risks inherent to specific disease states.

Physiologic changes from anesthetics

Surgeons should be aware of the basic physiologic effects of the anesthetics given during endourologic procedures.

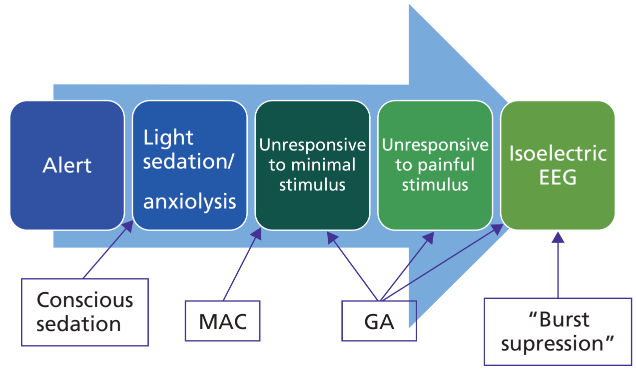

Figure 8.2 Spectrum of anesthesia. GA, general anesthesia; MAC, monitored anesthesia care; EEG, electroencephalogram.

Sedation

This technique encompasses a spectrum from light anxiolysis to heavy sedation in which the patient must be aroused to respond (Figure 8.2). If the patient has become unresponsive to pain and other arousal, due to sedative effects, then the anesthetic is defined as "general." Usually a combination of benzodiazepines, opioids, and other intravenous sedative hypnotics, such as propofol or alpha-2 agonists, may be used. Varying degrees of respiratory suppression and cardiovascular depression (mild at sedative doses) can occur, depending on the agents and combinations used.

When determining patient "tolerance" of sedation, it must be considered whether the patient has known or suspected obstructive sleep apnea that may be exacerbated during sedation (especially among the morbidly obese). The hypoventilation that occurs with progressive sedation leads to hypercarbia, which is well-tolerated by most patients, but can be life-threatening for patients with severe pulmonary hypertension due to the pulmonary vasoconstriction and right heart failure it precipitates. Patients with sickle cell anemia also tolerate hypercapnia and hypoxemia poorly due to the propensity of hemoglobin S to further decrease oxygen-carrying capacity under such conditions. With decreasing oxygen levels and the resultant increase in arterial carbon dioxide tension, intracranial pressure could increase to dangerous levels, especially if there is preexisting intracranial pathology. If any of these conditions are present, airway management with controlled ventilation must be considered (Figure 8.3).

General anesthesia

There are a myriad of physiologic changes that occur under GA. These depend upon the specific anesthetic agents and technique used, as well as the physiology of a specific patient and the details of the procedure. This

section will highlight *general* changes of highest impact by system (Table 8.4).

GA means that a patient is rendered unconscious and unresponsive to stimuli. Airway management and ventilatory support that are required vary depending upon the patient and surgical site (Figure 8.3). Muscle relaxation may or may not be a component of GA. If NMB is not required, e.g. as with retrieval of lower ureteral stones or simple ureteral stent placement, then airway management may utilize the native airway, with oxygen supplementation, and total intravenous anesthesia (TIVA). Alternatively, the airway may be managed with the insertion of a laryngeal mask airway device, which is a cuffed mask that sits above the glottic opening in the posterior hypopharynx, with a tube conduit exiting the oropharynx. Several manufacturers make these devices that connect to the anesthesia breathing circuit to allow delivery of oxygen and anesthetic vapors, either during spontaneous or assisted hand ventilation modes. This device lowers the risk of injury to the larynx or trachea from endotracheal tube placement, and also allows for a lighter anesthetic, due to lack of tracheal or carinal stimulation. Unfortunately, the device does not reliably protect against aspiration of gastric contents, as there is no cuffed tube sealing the upper trachea from the oropharynx, and therefore is not appropriate for patients at elevated risk for aspiration. This includes patients who have not fasted for 6 or more hours (solids), patients with gastroparesis and delayed gastric emptying, or those who have recently vomited. Although these laryngeal mask devices can be used with neuromuscular blocking drugs, this technique requires positive pressure ventilation through a partially unprotected airway, possibly increasing the likelihood of aspiration as well as loss of ventilatory pressure and volume from the breathing circuit. Few anesthesiologists choose this technique; however, some will use a low positive pressure assist ventilatory technique to achieve higher tidal volumes than with unassisted, anesthetized, spontaneous ventilation. Many anesthesiologists, though, prefer to have patients spontaneously ventilate through a laryngeal mask device, which poses risks in that this technique increases the possibility of atelectasis under GA if inadequate tidal volumes and minute ventilation occur.

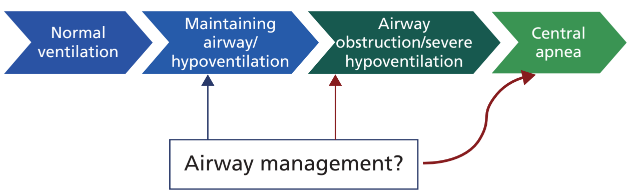

Figure 8.3 Effects of anesthetics on breathing.

If NMB is employed during GA, the airway must be managed with endotracheal intubation such that the patient is mechanically ventilated. An endotracheal tube allows for positive pressure ventilation with higher airway pressures than manageable with a laryngeal mask device. It is a definitive airway for prone and lateral positioning and is unlikely to be dislodged if secured in place. This technique also provides better protection against pulmonary aspiration, provided reversal of NMB is timed well with emergence from GA.

Table 8.4 Effects of general anesthesia.

Respiratory	Decrease in functional residual capacity
	Increased atelectasis and V/Q mismatch with possible hypoxemia
	Decrease in minute ventilation (due to drug effects) – offset with controlled mechanical ventilation
	Decrease in airway resistance (with most volatile anesthetics, though tracheal ventilation may counteract this)
Cardiovascular	Decrease in systemic vascular resistance in response to inhaled and most IV agents
	Decrease in venous return
	Decrease in blood pressure due to the above
	Decrease in stroke volume (usually following increased heart rate)
Renal	Decrease in renal blood flow (primarily due to decreased cardiac output and systemic vascular resistance), glomerular filtration rate, and urine output
Neurohormonal	Increased activity of sympathetic nervous system
	Increase in stress hormone release – catecholamines, cortisol, vasopressin, aldosterone, renin–angiotensin
	Blunted autonomic nervous system function in response to insult
Thermoregulation	Most frequently loss of heat to radiation, conduction, evaporation, and convection, with redistribution of blood flow to periphery
	Lowered threshold of hypothalamus for triggering heat conserving measures (shivering and vasoconstriction)

Neuroaxial anesthesia (spinal and epidural)

Both these techniques can induce significant changes in a patient's cardiovascular physiology, and to some degree respiratory physiology, and should not be considered benign or always less "risky" than GA. A meta-analysis of older data demonstrated a decrease in all-cause mortality by 30% in patients receiving neuroaxial blockade as opposed to GA in orthopedic, urologic, general, and vascular surgical procedures. This study also showed a decrease in risk of venous thromboembolism, MI, bleeding complications, pneumonia, respiratory depression, and renal failure as well, although the methods and age of this study limit its widespread applicability [54]. Nonetheless, many practitioners prefer to avoid intubation and/or GA when possible in patients with significant pulmonary comorbidities, even for lower risk procedures, in attempts to avoid atelectasis and airway irritation, and increased risk of postoperative pulmonary complications (PPCs). The American College of Physicians' guideline on reducing PPCs in noncardiac surgery identifies patients undergoing GA as higher risk for PPCs [55], and recommends evaluation for other concomitant risk factors. The guidelines also recommend that these patients receive pre- and post-operative interventions to reduce pulmonary complications, such as triple cough exercises, incentive spirometry, and early ambulation postoperatively.

A spinal anesthetic, or subarachnoid block (SAB), involves the introduction of a small dose of local anesthetic (lidocaine, bupivicaine, or others) with occasional adjuvants, such as opioids, epinephrine, or clonidine, into the subarachnoid space and cerebrospinal fluid at the level of the *cauda equina* (lumbar interspaces L3–4 or L4–5) with a longer, small gauge needle (22–27G). Local anesthetic and adjuvants are chosen based on expected duration of the procedure, postoperative disposition of the patient (to home vs inpatient), and anticipated dermatomal level of surgical stimulation. Baricity and dose of the local anesthetic injected also influence the extent and duration of anesthesia. Spinal anesthesia typically has a quick onset and high rate of success, with a time frame usually of 1–4 h of surgical anesthesia. Unless an adjuvant long-acting opioid is injected, e.g. morphine (which should not be used in outpatients due to the potential for late respiratory depression), SAB does not provide significant postoperative analgesia. With this, another parenteral analgesic may be needed to provide a sufficient "bridge" of analgesia until the patient is ready to take oral analgesics.

Epidural anesthesia involves injection of larger volumes and doses of local anesthetics as well as adjuvants into the epidural space which lies just outside the dural sac. Such larger volumes are needed to ensure significant spread of the local anesthetic within the dural area to reach nerve roots. Frequently, a small catheter is left in the epidural space for redosing. One drawback of epidural anesthesia for endourologic procedures involving the perineum is occasional "sacral sparing" that may occur. This is a deficit of anesthesia in the sacral dermatomes due to the larger size of the L5, S1, and S2 nerve roots [56]. A uniform block is dependent on spread of the local anesthetic (LA) and other drugs around multiple nerve roots, and fibrous and venous tissue in the dural space. If there is postsurgical or other scarring within this space, the spread of local anesthetic and subsequent analgesia can be hindered, resulting in a slower onset of action relative to SAB. This may be advantageous in that a smaller band of anesthesia may be achieved, if desired, by using smaller doses of local anesthetics. Similar to spinal anesthesia, the addition of opioids and other adjuvants, i.e. alpha-2-agonists, epinephrine and clonidine, to the local anesthetic may increase the "density" or effectiveness of the block, as well as increase the duration. Choice of specific local anesthetic and its dose affect the duration and density of the block, as well as the extent of motor block achieved. Level of placement of the catheter, age of patient, and patient position during initiation of the block also affect block spread and duration. Larger volumes and doses make LA toxicity a more likely complication with epidural anesthesia, though this is rare when incremental dosing is achieved and after a negative "test dose" of the catheter. Incremental dosing through the catheter may also make controlling the change in hemodynamics over a gradual period more achievable with epidural anesthesia.

A "combined spinal–epidural" (CSE) combines the techniques utilizing initial intrathecal SAB with subsequent placement of an epidural catheter in the lumbar region. The catheter is left in place for use if the surgical procedure exceeds the duration of the SAB. The technique is usually accomplished through a specialized CSE needle set that includes a larger gauge epidural Tuohy needle used to identify the epidural space, through which a longer, thinner needle can be passed to enter the subarachnoid space through *dura mater*. The spinal needle is removed after dosing the intrathecal local anesthetics, and the epidural catheter placed for later dosing. A CSE combines the reliability and speed of onset of SAB plus the flexibility of longer term redosing of the epidural catheter.

Tables 8.5 and 8.6 give the approximate duration of spinal and epidural anesthesia using different local anesthetics.

With regards to dermatomal levels for ureteroscopy and PCNL, the neuroanatomic innervations of the renal pelvis and ureters must be considered. Sympathetic innervation of the kidney arises from spinal segments T8 through L1 as preganglionic fibers that synapse in the celiac and aorticorenal ganglia, giving rise to the postsynaptic fibers that travel along the renal artery to

Table 8.5 Dose and duration of local anesthetics used for spinal anesthesia (reproduced from Bernards, C.M. Epidural and spinal anesthesia. In: Barash, P.G., *et al*., eds. *Clinical Anesthesia*, 6th edn. Philadelphia: Lippincott Williams & Wilkins, p. 941, with permission).

		Duration of sensory block		
Drug	Dose (mg)[a]	Two-dermatome regression (min)[b]	Complete resolution (min)[b]	Prolongation by adrenergic agonists (%)[c]
Procaine	50–200	30–50	90–120	30–50
Chloroprocaine	30–100	30–50	70–150	NR
Lidocaine	25–100	40–100	140–240	20–50
Bupivacaine	5–20	90–140	240–380	20–50
Tetracaine	5–20	90–140	240–380	50–100

NR, not recommended.
[a]The lowest doses are used primarily for very restricted blocks (e.g. saddle block), lest they become too dilute to be effective.
[b]Duration is influenced by dose and block height. The duration of surgical anesthesia will obviously depend on the surgical site.
[c]The effect of adrenergic agonists depends on the dose and choice of agonist. Prolongation is greatest at lumbar and sacral dermatomes and least at thoracic dermatomes.

Table 8.6 Local anesthetics used for surgical epidural block (reproduced from Bernards, C.M. Epidural and spinal anesthesia. In: Barash, P.G., *et al*., eds. *Clinical Anesthesia*, 6th edn. Philadelphia: Lippincott Williams & Wilkins, p. 942, with permission).

Publisher's Note:

[a]These concentrations are recommended for surgical anesthesia; more dilute concentrations are appropriate for epidural analgesia.

reach their targets. Renal parasympathetic innervation is from vagal nerve fibers that also travel along the renal artery. The ureters receive their sympathetic input from spinal segments T10 to L2, and parasympathetics from the S2 to S4 nerve roots. Painful stimuli from either distension or mucosal irritation will travel with the sympathetic fibers, as well as the ureters, to radiate up to the level of the upper kidney [57]. For this reason, any neuroaxial anesthetic should cover at least through sensory level T8. This ensures that adequate anesthesia is provided several levels above the surgical site and that skin and chest wall sensory levels above the area where somatic stimulation will occur with instrumentation are also covered (T6).

Physiologic effects of both SAB and epidural anesthesia are similar, although they occur more rapidly with SAB. Cardiovascular effects include decrease in α_1 and β sympathetic stimulation effects ("sympathectomy") from the level of two to four dermatomes above the sensory block level achieved, leading to decreased blood pressure. Venous and arterial blood vessel tone both decrease. The decrease, particularly in venous return, that results can cause a significant drop in cardiac output if the patient is volume depleted [56]. The decrease in systemic vascular resistance can be beneficial for the patient with cardiac disease in that cardiac workload is reduced, if MAP and cardiac perfusion do not also drop excessively. Since cardiac perfusion is heavily dependent on diastolic filling pressure, a significant drop in MAP can have deleterious consequences in those with either significant coronary artery disease or low cardiac reserve.

Table 8.7 American Society of Regional Anesthesia Guidelines (modified and reproduced from Horlocker *et al*. p. 101, with permission).

Thromboprophylaxis	Neuroaxial technique
Antiplatelet medications	NSAIDs: no contraindication Discontinue ticlopidine 14 days, clopidogrel 7 days, GP IIb/IIIa inhibitors 8–48 h in advance
UFH: subcutaneous	No contraindication with twice daily dosing and total daily dose <10 000 U; consider delaying heparin until after block if technical difficulty anticipated.
UFH: intravenous	Heparinize 1 h after regional technique; remove catheter 2–4 h after last heparin dose. No mandatory delay if traumatic
LMWH	Twice daily dosing: LMWH can be resumed 24 h after surgery. Remove catheter 2 h *before* first LMWH dose
	Single daily dosing: neuroaxial technique 10–12 h after LMWH; next dose 4 h after needle or catheter placement
	Therapeutic dose: delay block for 24 h
Warfarin	Normal INR (before neuroaxial technique); remove catheter when INR ≤1.5 (at initiation of therapy)
Fondaparinux	Single injection, atraumatic needle placement or alternate thromboprophylaxis. Avoid indwelling catheters
Direct thrombin inhibitors	Insufficient information. Suggest avoidance of neuroaxial techniques
Thrombolytics	Absolute contraindication
Herbal therapy (garlic, ginseng, ginko)	No evidence for mandatory discontinuation before neuroaxial technique; be aware of potential drug interactions

UFH, unfractionated heparin; LMWH, low molecular weight heparin.

Pulmonary function is not altered clinically during neuroaxial anesthesia in any but those with the most severe pulmonary disease. Tidal volumes are unchanged, and vital capacity decreases slightly during SAB or epidural anesthesia, as a result of paralysis of abdominal muscles. Those with severe respiratory compromise may suffer ineffective cough to clear secretions, due to paralysis of expiratory muscles [58].

Another important issue to be considered with regards to neuraxial anesthesia is anticoagulation, coagulopathy, or antiplatelet therapy, and the risk of epidural hematoma formation. Although rare, if not diagnosed and treated quickly, epidural hematoma can lead to significant permanent neurologic injury, including paraplegia. This is especially pertinent in patients treated chronically with either antiplatelet or anticoagulant agents. According to the American Society of Regional Anesthesia and Pain Management (ASRA), the estimated incidence of epidural hematoma in patients undergoing spinal anesthesia is less than 1 in 220 000, and less than 1 in 150 000 for epidural anesthetics [59]. ASRA recently published "guidelines" on the performance of regional anesthesia in patients on antithrombotic or thrombolytic therapy [59]. Due to the rarity of epidural or spinal hematoma, there are no prospectively controlled data on the subject, and the guidelines are based on case reports, expert opinion, hematology, pharmacology, clinical series, and risk factors for surgical bleeding [60]. The document does caution that it should be considered a "consensus statement" rather than strict guidelines. The risk to benefit analysis must be considered for each individual in light of alternative anesthetic techniques. Table 8.7 summarizes the ASRA recommendations regarding neuroaxial techniques.

Complications and issues for recovery

With both PCNL and ureteroscopy, the acuity of urologic or renal dysfunction due to obstructive uropathy or infection poses challenges to the provision of anesthesia. Decrease in renal function slows clearance and excretion of a number of anesthetic agents and potentiates the duration of action of their active metabolites. Such agents include meperidine, fentanyl, and morphine, and NMB drugs, specifically rocuronium, vecuronium, and pancuronium. This predisposes the patient to prolonged recovery, postoperative mechanical ventilation, and fluid overload. Sevoflurane, a newer inhaled anesthetic, reacts with strong bases and water in the carbon dioxide absorbents when passing through the anesthetic circuit to form Compound A, which has been shown to cause renal dysfunction in animal models. This agent, however,

has been demonstrated safe in humans and not shown to cause any more renal dysfunction than other inhaled halogenated agents [61], including in patients with pre-existing renal dysfunction.

Patients with evolving urosepsis pose additional difficulties in that infection and fever increase metabolic rate and oxygen demand. Significant sepsis has been considered a relative contraindication for neuraxial anesthesia (spinal or epidural) for fear of introducing the infection from the bloodstream to the intrathecal space, and causing meningitis; however, that link has never been clearly established and remains controversial [62]. Furthermore, patient comorbidities may influence the surgical and/or anesthetic approach to the stone. For example, patients who need to remain on dual antiplatelet therapy perioperatively for prevention of intracoronary stent thrombosis prohibit neuraxial blockade. Also, many myelopathic patients with chronic nephrolithiasis may have developed tolerance to opioids due to chronic use, which complicates their anesthetic management and recovery.

Percutaneous nephrolithotomy

Surgical complications of PCNL are often minor and include pain (49%), fever (30%), urinary infection (11%), and colic (4%) [10, 63]. Septicemia (4.1%) and bleeding sufficient to require transfusion (2.7%) are the most common major complications of PCNL [63]. Roth and Beckmann cite rare incidences of additional complications in PCNL, including pseudoaneurysm (0.5–1.2%), pelvic or ureteral tears (5–15%), bowel injury (0.1%), pneumothorax or hemothorax (0.1% to 3%), urosepsis (0.3%), MI (0.1–0.4%), and rarely splenic or hepatic injury [64]. When radiographic contrast agents are used, the possibility of allergic reactions to the iodinated dyes must also be considered. Furthermore, latex allergy must be strongly suspected in myelopathic patients who repeatedly self-catheterize to relieve urinary retention, and the operating room must be prepared as a latex free environment. Due to repeated exposures, these patients may be at high risk for anaphylaxis at any point during the procedure [65, 66].

Additional issues complicating PCNL include blood transfusion that may become necessary as a result of pre-existing anemia and/or greater than expected blood loss. An uncomplicated single stage, single puncture PCNL averages very low blood loss; however, there have been incidences where loss of greater than 1 L has been reported [67, 68]. The incidence of transfusion with PCNL lies between 2% and 11%, [36, 64], but may exceed 23% in some groups of patients [67]. Multiple renal punctures and renal pelvic perforation are associated with a twofold greater blood loss [68]. Conversely, the presence of a pre-existing nephrostomy tract decreases this risk by half. Neither puncture site, hypertension, renal insufficiency, infection, nor characteristics of the stone, such as size, location, or composition, increase bleeding risk [67]. Surgery should be rescheduled or, at a minimum, blood for transfusion should be available for patients with pre-existing anemia or coagulopathy. Patients taking anticoagulant or antiplatelet medication require special consideration as the cessation of these medications could have severe consequences [38].

Ureteroscopy

GA for ureteroscopy does present challenges in patients with morbid obesity or multiple medical problems that have a diminished tolerance for the physiologic changes associated with this technique. In patients with severe cardiac disease, sudden hemodynamic changes need to be avoided. Hence, neuroaxial anesthesia *may* be a preferable method of anesthesia [54].

If sepsis is a concurrent issue with the patient, GA or sedation may be a better option to avoid the risk of inadvertent introduction of bloodstream infections into the subarachnoid space as mentioned [20]. Monitored anesthesia care (MAC) may provide heavy sedation but may become GA without an endotracheal tube as the patient loses consciousness (Figure 8.2). Several agents are typically utilized for this technique, and include a combination of narcotics and sedative hypnotics where the desired effect of each medication is potentiated and negative side effects minimized, provided there is effective renal clearance. For example, utilizing remifentanyl, propofol, or dexmedetomidine with a combination of narcotics or benzodiazepines for heavy MAC/sedation, either individually or in combination, has been shown to decrease anesthetic induction and postoperative recovery times during lithotripsy [65]. Rapid recovery, however, is dependent upon adequate redistribution and elimination of these agents, as well as their active metabolites. Excretion of these active metabolites is largely dependent upon adequate renal function. This is especially important for narcotics such as morphine, hydromorphone, and meperidine, as well as many NMB agents.

Conclusions

Anesthetic techniques for ureteroscopy and PCNL must be planned based on patient comorbidities, details of surgical anatomy, as well as surgeon and anesthesiologist preference. Multiple techniques have been used successfully and safely. Many patients with nephrolithiasis have multiple comorbidities that need to be considered. Examples noted include diabetes, hypertension, and obesity. Lastly, positioning for PCNL adds an element of complexity for which careful preoperative planning is required.

CHAPTER 9

Organizing the Operating Room for Percutaneous and Ureteroscopic Procedures and Laparoscopy

Ravindra B. Sabnis & Shashikant Mishra
Mulgibhai Patel Urological Hospital, Nadiad, Gujarat, India

Introduction

The working of the operation room (OR) needs specialized planning and execution. A combined "civil–mechanical–electrical–electronic–biomedical" combined effort is required, coordinated by the needs, preferences, and safety of the medical/surgical team. Apart from the scarcity of practical publications and details in this area, the highly technical nature of many of the issues, and the difficulty of communicating them, often result in mistakes in planning being made at a very simple level.

OR complexes are designed and built to carry out investigative, diagnostic, therapeutic, and palliative procedures of varying degrees of invasiveness. Since the introduction and widespread application of minimally invasive surgery, the design of a modern OR has changed dramatically. Adapting the modern OR for endourology is a challenge that begins with the more general problem of designing the OR. There is a need for safety, convenience, and economy in planning a dedicated endourology fluoroscopy-compatible OR complex. It is necessary that planning is perfect, keeping in mind future needs, as subsequent changes or renovations are tedious and pose tremendous economic burden [1].

In the current era of information technology, audiovisual (AV) recording, and telementoring have become a frequently used teaching and training aid in operative surgery (see Chapter 3). Most surgical meetings today devote a major session to the live operative workshop. Unfortunately, many video recordings are of poor quality, and often, because of the constraints of the equipment and the operating environments, do not demonstrate the principles of the technique as well as the presenter intended. The other problem is economic restriction, especially in semi-government aided or private hospitals. These shortcomings are severely felt, especially in a tertiary care teaching hospital, as surgical workshops are held quite regularly and AV transmission consumes a large chunk of the investment. In addition to being used to relay the operation, the teacher can access the video display to monitor the progress of the operation, and it can be used to teach residents in the OR about the procedure.

In this chapter, we intend to present a comprehensive description of the planning of a state-of-the-art endourology-dedicated OR, with both high-class OR equipment and technology-driven OR data management.

Designing and planning a dedicated operating room

The design and layout of the OR room is extremely important. The state-of-the art design enables hassle-free movement of equipment, surgeon ease in viewing multiple screens, and efficient data archival, management, and relay system. It is necessary to anticipate the average number of procedures that will be carried out. It is better to plan bearing the next 10 years in mind.

Meeting these challenges requires a multidisciplinary team and a well-planned process that addresses all aspects from long-term goals to exacting details. Design and construction firms apply experience and expertise

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

to handle the intricacies of the dedicated OR. Select an architect and construction manager with considerable healthcare experience, including of surgical suites and ORs. Architect, engineer, equipment planner, construction manager, and key equipment vendors should all be included in the team [2]. Strategic equipment placement is essential to increase efficiency and safety within the surgical space. Equipment booms and other ceiling-supported equipment are used increasingly in ORs because of the advantages they offer [3]. Equipment booms are ceiling-mounted, articulated arms that support much of the OR equipment, like lithotripters, light sources, endocameras, electrocautery equipment, anesthetic gas connections, and electric plug points. The booms, which can move in every direction, significantly reduce clutter and interconnect equipment, freeing floor space and simplifying cleaning. They utilize the space above the false ceiling, thereby enhancing sterile set-up and reducing maintenance as a result of cable breakage. Booms, however, require a significant amount of structural support, which must be coordinated with the lighting, mechanical, and electrical systems above the false ceiling.

General design for a fluoroscopy-compatible endoscopic operating room

Size

The size of a general OR is $20 \times 20 \times 10$ feet. Since endourologic procedures use large equipment, like a C-arm, laser, ultrasound machine, and workstation, the recommended size of a dedicated endoscopic OR is $23 \times 23 \times 12$ feet.

Ceiling

The floor-to-false ceiling height should be around 12 feet. The overall height of the OR should be around 14 feet to give an over-ceiling space of 2 feet. Individual cassettes made of painted sheet steel are clipped into the grid to form a suspended metal ceiling. The individual cassettes can be removed and reinstalled to permit maintenance and refitting work.

The over-ceiling plan is an important feature. This space includes:

• Cables for various multiple equipment booms, such as oxygen, nitrous oxide, compressed air, vacuum, electrical wires.

• Air conditioning pipelines. The ceiling air supply with the sterile air distributor is one of the most important elements for hygiene in the operating room. Bacteria, viruses, and dust particles are trapped immediately before the air enters the room. The sterile air distributor generates a homogenous and low-turbulence displacement flow. The inner air supply area remains free from contaminants drawn in from the room environment. In this way the area around the operating table is kept in a high state of cleanliness during the operation, with an extremely low pathogen level of less than 10 colony-forming units/m^3. The sterile air distributors can be easily detached or swung away for quick and economic filter changes.

• Data relay wires in various hanging arms.

Pendant services

Two ceiling pendants for pipeline services should be designed; one for the surgical team and one for the anesthesiologist. The anesthetic pendant should be retractable, have limited lateral movement, and provide a shelf for monitoring equipment. It should have oxygen, nitrous oxide, four bar pressure medical compressed air, medical vacuum, scavenging terminal outlets, and at least four electric sockets. The surgeon pendent or cart should have the capacity to hold video camera electronics, a light source, and various recording devices such as a VCR, printer, or video disc recorder. Moreover, some carts also have room to hold the laparoscopic insufflator and electrocautery units.

Floor

There should be a central drain outlet from the floor, centered underneath the OR table. The floor should have a slight tilt from all the walls, converging at the water drain outlet. The floor surface must be slip resistant, strong, and impervious, with minimum joints, e.g. mosaic with copper plates for antistatic effect or jointless conductive tiles/terrazzo, linoleum etc. The recommended minimum conductivity is 1 mOhm and maximum 10 mOhm.

Walls

The radiation protection of a general-purpose fluoroscopy suite necessitates a wall thickness in all directions equivalent to 2 mm of lead (15 cm of concrete or 25 cm of brick with plaster). While lead is always accepted as the standard material for radiation protection, ordinary building materials may be equally suitable provided they are thick enough. As for the floor, the surface of the walls must be slip resistant, strong, and impervious, with minimum joints. Laminated polyester or smooth paint provides a seamless wall surface; tiles can break and epoxy paint can chip. Light color (off white, light blue or green) washable paint is ideal. There should be provision for an X-ray film illuminator, wall-mounted camera, plasma screen, and drawers for endoscopic disposables, recessed into the wall.

Main door

The main door to the OR must be of adequate width (1.2–1.5 m) to facilitate smooth patient trolley, laser, C-arm unit, and ultrasonography machine entry and exit. Sliding doors are preferred as these do not generate air currents.

Lighting

Different levels of lighting are necessary in the OR and a means of dimming light may be needed during endoscopic procedures. The flat TFT monitor display for endocamera vision requires the installation of dimmable lighting to create optimum light levels. Color-corrected fluorescent lamps are preferred to produce even illumination of at least 500 Lux at working height, with minimal glare. In the operating area, overhead light should be shadowless and give 25 000–125 000 Lux of light (50 000–100 000 Lux at the center and at least 15 000 Lux at the periphery), as in the general OR. Light emitting diode (LED) light provides a unique multicolor temperature facility, which proves helpful during open surgery, which may be required in the event of an endoscopic complication. LED light has the advantage of lower heat generation, adjustable light characteristics, and unlimited lifespan. Lights should be freely movable both in the horizontal and vertical planes, and for this movement equipment booms are generally preferred.

Operating room table

The OR should have a mobile, modular operating table with electronically controlled hydraulic drive, battery and mains operation, and of adequate width and weight-bearing capacity. It should have a stable base construction, rotatable, top and large twin disk castors for easy maneuverability. The operating tabletop needs to be subdivided into multiple sections; head plate, upper back plate, lower back plate, seat plate, and leg plates for lithotomy position. To be compatible with fluoroscopy, the entire tabletop should be devoid of cross bars. Provision for kidney bridge elevation is helpful if open exploration is required. There should be multilayered radiolucent foam padding for patient comfort and safety.

C-arm

A mobile C-arm unit is essential in an OR dedicated to urology. It should have balanced and graduated movements at any angle. It should provide a high-quality image to allow quick and precise diagnosis (brightness should be monitored so that image quality is not affected by changing lighting environments). Functions of the image intensifier should include DICOM imaging capabilities, last image hold memory, image processing, and text/graphics. Image display should be on a high-resolution TFT monitor. The data output from the C-arm may also be connected to one of the hanging screen monitors so as to be in easy view of the operating surgeon.

Sterilization (see also Chapter 1)

There should be a separate room for cleaning and disinfection of endoscopic instruments, which should have adequate ventilation to exhaust toxic vapors and airborne pathogens. Automated processing disinfection machines for endoscopic instruments are desirable. However, there should also be provision for manual rinsing and cleaning. If endoscopes and other accessories cannot be autoclaved, there needs to be provision for chemical sterilization and ethylene oxide (ETC). Endoscopic procedures need delicate and expensive equipment, like telescopes, flexible ureteroscopes, and flexible nephroscopes. Rapid sterilization is required if many procedures are to be performed in a day, and for this we recommend a Sterrad sterilization system close to the OR, which provides a high level of sterilization within a processing time of half an hour.

Operating room configuration for endourologic procedure

This configuration of an endourology OR is different from that of a general OR, as equipment has to be strategically located. This will minimize procedural time by allowing intuitive control and shorter changeover times, as equipment settings can be freely defined and activated. The OR should integrate cameras, lights, video conferencing units, endoscopic and anesthetic equipment, C-arm and the operating table, and all should be capable of being operated from the sterile area.

The anesthetic trolley should be movable on a mobile cart supported by the anesthesiologist's equipment boom, and located at the cephalad end of the patient on the same side as the procedure.

There should be a minimum of three hanging display screen monitors, supported by a boom, moveable in all directions, and placed in front of the surgeon (Figures 9.1 and 9.2). The display monitors should be interconnected with changeable viewing between fluoroscopic image, endovision image, ultrasound image, and HIMS image (Hospital Information Management System).

Quite often both kidneys need to be operated on under the same anesthesia. This can be done in two ways. In the first, the C-arm unit remains fixed while

the anesthesia boom and table rotate through 180°. In the second, the anesthesia trolley and table remain fixed, while the surgeon's position changes. Display screens accordingly also change the direction in which they face. The light cable source, lithotripsy device, endocamera cable, and irrigation tubing are attached to the equipment boom on the right side behind the surgeon.

Figure 9.2 shows the essentials of a strategic equipment set-up for left percutaneous nephrolithotomy (PCNL).

Modular operating theatre

The prefabricated modular operating theatre offers the advantage of speedy construction combined with design of the highest quality and standards, while allowing for future expansion and development in surgical technique. The standard package includes an operating table, operating lights, endoscopy equipment, and a range of monitors that surround the patient [4].

Two dedicated endourology modular ORs are currently available, one from Karl Storz (KARL STORZ OR1™) and the other from Richard Wolf GmBH (CORE™), which can be installed on demand by the respective technical teams. The KARL STORZ OR1™ provides the modular operating room layout for performing minimally invasive endourologic and laparoscopic procedures. Key features include optimal picture quality from various camera systems and other signal sources, integration of Karl Storz endoscopic equipment, the full range of functions of devices and peripheral systems made by other manufacturers, such as the OR table and room lighting, and simple and secure documentation of intraoperative recordings and the OR environment at a central location.

CORE™ has a modular, networked structure to link various devices in the operating theatre. The system provides interactive monitoring and centralized control from a single operator panel, and has speaker-independent voice control that enables devices such as cameras, lights, video conferencing units, PACS, high-frequency equipment, room functions, and the operating table to be operated from the sterile area. Medimage, a digital patient imaging and document management system, facilitates intraoperative visualization of preop-

erative image data on monitors located within the operating area.

Data management (see Chapter 3)

In the current era of information technology, data capture, archival, and relay have become a frequently used teaching and training aid in operative surgery [5]. The ability to project computer and video information to a class or auditorium is now almost essential in many tertiary care hospitals, driven by the exponential increase in computer usage by both teaching staff and students. This need for versatile, large-screen electronic display systems is the dominant factor influencing the design of AV facilities, and typically the most expensive single equipment element of any presentation system. Other technologies have grown up around the electronic display capability, and the expectations of users have become more sophisticated.

Data capture

A surgical video system (SVS) is an integration of components used to perform minimally invasive surgery. In the operating room, an SVS consists of an endoscope, attached video camera, light source, video processor, and one or more video displays.

Endoscope

Digital videocystoscopy and ureterorenoscopy use high-resolution monochrome CCD chip technology [5]. Three-chip systems provide better overall image quality than one-chip systems. The use of high-definition cameras and monitors during minimally invasive procedures can provide the surgeon and operating team with more than twice the resolution of standard definition systems. If a high-definition camera is selected, it is imperative to invest in computer hardware and software capable of editing and outputting high-definition video.

video camera

There are many options for avoiding poor quality video capture in surgical procedures on the body surface. The simplest and most cost-effective method in this setting is to employ a video camera mounted on a tripod (surface camera) or installed on the wall with movable pulley (overhead camera). These are available from any

number of consumer electronics outlets and in a variety of formats. Although it is possible to obtain reasonable quality video recordings by using the automatic exposure settings on most cameras, this often requires diversion of the operating light away from the operative field to avoid overexposure of the image. Almost all cameras, however, will have a predefined setting for bright environments, and this is an ideal alternative to use in this situation.

Video light source

Additional advances in imaging have resulted from the use of a high-intensity light source, generated from either halogen or xenon sources. The ability to adjust light intensity using several mechanisms has been a recent advance. Newer CCDs or image sensor-based endoscopic cameras feature electronic exposure. Recent innovations in illumination technology use single- or multi-point shadow-inducing systems.

Video and image capture

When performing endourologic surgery, video capture is not usually an issue. A signal can be taken directly from the lineout plug of the camera-processing unit and inputted directly into an analog or digital VCR using an s-video connection. Some endoscopic video processors come equipped with digital video (DV) outputs which capture a high-definition video.

Of importance in a dedicated OR is an efficient to-and-fro data capture for HIMS. HIMS uses a network of computers to gather, process, and retrieve patient care and administrative information for all hospital activities to satisfy the functional requirements of all those involved in the care of patients. It is also helpful to the hospital authorities for developing comprehensive healthcare policies. HIMS incorporates an integrated computerized clinical information system for improved hospital administration and patient healthcare. It also provides an accurate, electronically stored medical record of the patient. There are innumerable software packages currently available for installing HIMS as per local preferences. The software has to be installed on all computers in the OR complex. A separate hardware for HIMS exists which has output for s-video and composite video. The output is connected to the OR panel and through it to the various data capturing units working during the procedure. In this way, multiple images and videos can be captured and stored in the patient data file for future references in HIMS. SVSs integrate a digital image capture system that allows the immediate capturing of still images from endoscopic procedures. A less expensive alternative is the digital still image capture adapter, which can be connected to endoscopic camera systems. Digital still images usually can be recorded in JPEG (.jpg; Joint Photographic Experts Group), TIFF (.tif; tagged image file format), or BMP (.bmp-bitmap) formats, depending on the necessary quality of the image to be edited (see Chapter 3).

Data archival

Customized OR software can be designed for individual needs. The following provides a general outline of the requirements of a data management system.

Workstation

In the modern OR, there should be an electronic workstation located in one corner. This workstation (Figure 9.3) has inputs via cables connected to the surface cameras, C-arm, ultrasound machine, and endovision camera. The cable input enters the OR panel where the composite AV signal is converted to s-video signal. The s-video output can be transmitted to any of the hanging display monitor (TFT screens) in front of the surgeon. Each screen has multiple cables, hence any image (fluoro/ endovision/HIMS) can be viewed on any screen. The workstation also has a video processor with digital video (DV) output. High-definition video [6] is thus captured and recorded on DVD for archiving and future editing. The OR panel is also connected via a two-way circuit to HIMS. The necessary information, including the history, examination, X-ray, and CT scan images can be relayed to the hanging display monitor in front of the surgeon during the operation. At the same time, the OR details can also be fed to HIMS for data archival. The workstation has three ISDN line connections.

Data capture

Endovision camera

A signal can be taken directly from the line-out plug of the endocamera processing unit and inputted directly into an OR panel on the workstation.

Surface camera

At least three surface cameras should be present in the OR for video capturing [7]. One camera is directed at the tabletop, and may be mounted on a light source or on a hanging boom. Another camera should be wall mounted near the ceiling, and provides a view of the complete OR. This camera can be zoomed in or out as required by remote control. The third camera should be on one of the TFT screens. This position captures the face of the surgeon and is important during video conferencing when the surgeon is performing the procedure while watching the screen and simultaneously

talking to the audience in the auditorium; these images will give the impression to the auditorium that the surgeon is facing and talking to them.

Fluoroscopic and ultrasound image

Most C-arm unit [8] and ultrasound machines have a coaxial output jack on the back of the device. To arrange for data transfer, the coaxial jacks need to be connected with a coaxial cable and connected to the OR panel.

Data relay

Various aspects need consideration for a state-of-the-art transmission relay system. Preliminary knowledge of the individual components of the relay system is essential for optimum utilization. These can be divided into components of local data relay and of the local and distant data relay system.

Local data relay components

The relay components are electrically interfaced to a control station within the OR. This control station has the capability to route voice, video, data, and physiologic information to and from the surgical suite. This capability is achieved through strategic equipment placement and an electrical infrastructure that allows the distribution of power and low-voltage wiring. Information is not only distributed within the operating room but also to remote locations such as image archiving systems (PACS), classroom, and auditorium.

Modulator

The AV signal is converted into a UHF signal so that it can be received through a TV antenna input. Various electronic modulators are commercially available.

- *Combiner* has two inputs that respectively receive an NTSC combined visual and audio signal and a DTV signal wherein the NTSC signal and the DTV signal are in adjacent channels. The combiner has sharply tuned filtering interposed between the inputs and the output, tuned to pass the DTV signal while reflecting the NTSC signal such that these combine to form the combined output signal.
- An *RF amplifier* is used to convert a low-power radiofrequency signal into a larger signal of significant power.
- *Audio mixer* is an electronic device for combining, routing, and changing the level, tone, and/or dynamics of audio signals. The modified signals (voltages or digital samples) are summed to produce the combined output signals.

• *Video mixer* is an electronic device used to combine or "mix" two or more (PAL or NTSC) video signals, then output the sum as one new composite video signal. The picture-in-picture (PIP) and picture-on-picture (POP) support unit allows users to watch TV channels or DVD movies together with the computer screen, if a PC is connected to this unit. The PIP zoom function allows the PC image to occupy the main screen, with a video subwindow inserted. This video subwindow can take one of three sizes: one-quarter, one-ninth, or one-sixteenth of the screen, and can be relocated anywhere on the screen. POP is designed for cable TV channel preview. The channel preview can be set as 3 × 3 or 4 × 4 matrix with up to 16 channels at a time.

Optical fiber composite overhead ground wire

This type of cable (OPGW) is used in the construction of electric power transmission and distribution lines. The optical fibers within the cable can be used for high-speed transmission of data. Because of the physical properties of image transference, optical fiber has a lower attenuation than coaxial cable and is not subject to electromagnetic interference.

Wireless local area network

Using electromagnetic waves, these networks (WiFi) allow wireless devices to communicate with one another through access points or antennae. The advantages of a wireless network are the lack of having to install a wired network and the ability to communicate with mobile users.

Local operating room data relay system

Most surgical meetings today devote a major session to the live operative workshop. Preliminary knowledge of the individual components of the relay system is essential for optimum utilization.

Control room

A small control room in the vicinity of the operating room is useful for the data relay system. The control room receives cable connection from all of the data capturing components, and can route voice, video, and data to and from the surgical suite. Information is not only distributed within the OR but also to remote locations such as image archiving systems, classroom, and auditorium. One such electrical circuitry is shown in Figure 9.4.

To channel transmit OR proceedings to remote places, the composite AV signals from the OR is first relayed via cables to the control room. Here the signal is passed through the modulator, combiner, and video mixer (Figure 9.5). The emerging RF signal is thus transmitted to remote places, such as the plasma screen recessed in

the wall of the OR. The operating surgeon through the microphone can interact with observers at remote places in a similar way. As described above, advanced video transmission features can be incorporated in the relay system; PIP and POP.

Similarly signals can be relayed from remote places to the OR (Figure 9.5). For example, the AV signal from the auditorium is sent to the modulator in the auditorium and the emerging RF signals are then relayed to control room (Figure 9.6). The signal is then sent to the modulator, combiner, and audio mixer. The final amplified RF signal can be relocated to any remote place, including transmission to the plasma screen in the OR.

Four clinical scenarios for local data relay are shown in Figure 9.5. The first shows a teacher in a remote location accessing the live operative video display to monitor the progress of an operation. The AV signals from the OR are relayed to the video mixer and modulator. The signal from the modulator is mixed in the combiner and the emerging RF signal is transmitted to the teacher's room. The teacher can order specific commands about the procedure from this remote location to the operating resident in the OR through a wireless microphone. The audio signal is relayed to the audio mixer, and then to the speaker installed in the OR or through the modulator, which creates the RF signal that is relayed into the OR through the installed LCD screen.

The second scenario shows a teacher who is operating in the OR and relaying AV signals to the classroom or the auditorium for a two-way interactive operative workshop. Here, the AV signal is relayed to the video mixer for POP support or directed to the video modulator and combiner. The selected signal is amplified, switched into an RF signal, and transmitted to the plasma screens or projectors in the auditorium or classroom. The audio feedback from the audience is collected through the microphones and relayed to the audio mixer. After passing through the modulator and combiner, the RF signal is displayed on the LCD screen in the OR or, after passing through the audio switcher, an audio signal is relayed through the speaker installed in the OR.

The third scenario shows a teacher or observer who is remotely monitoring the progress in various ORs. The video signal from the various ORs is transmitted to the modulator and combiner, and as an RF signal is then sent to the teacher. The teacher can select the individual OR they wish to monitor using a channel selector.

The last scenario shows a surgeon who wishes to watch the OR proceedings on DVD. The video signal from the OR is fed into the video mixer. The output signal is then recorded by the DVD recorder, and a DVD can then be given to the surgeon to watch.

For teleconferencing to distant places and countries, an ISDN network facility needs to be connected to the computer in the workstation in the OR. Just like a regular telephone line, the ISDN enables the OR transmission to be dialed to any ISDN location anywhere in the world. Through the B channel, the ISDN line can support simultaneous two-way communication for two devices, such as a computer and a telephone, or a computer and a video camera for teleconferencing. Through the ISDN line, data can be sent to remote locations and at the same be received by the workstation, sent to the control room, and then transmitted anywhere else required.

Conclusions

A dedicated OR design is essential for endourology and allows efficient state-of-the-art care in the modern infor-

mation technology era. The older cart-based paradigm restricts the ergonomic configuration of the OR and creates potential mechanical, electrical, and biologic hazards to the patient and OR staff. In order to decrease clutter, ease personnel movement, improve ergonomics, maintain the sterile field, and facilitate the use of advanced imaging, an appropriately designed OR is essential. These design elements may prove to be critical to the next generation of dedicated fluoroscopy-compatible endourology suites, and will facilitate further advances in procedures.

The data archival, management and relay system enables efficient and cost-effective transmission of data. This arrangement has been used extensively in our own hospital during the last 5 years, with resultant high-quality video recordings being presented at a number of national and international surgical meetings. In addition to being used for recording video, members of the OR staff can refer to the video display to monitor the progress of the operation, and it can be used as a teaching aid for residents present in the OR during the procedure.

CHAPTER 10

Patient Positioning for Supine Access

José Gabriel Valdivia-Uría
Hospital Clínico Universitario “Lozano Blesa”, Zaragoza, Spain

Introduction

It was in 1954 that Wickbom [1] performed the first antegrade pyelography by direct renal pelvis puncture [1], and the following year Goodwin *et al*. reported the first percutaneous nephrostomy in hydronephrotic kidneys [2]. At that stage radiologists considered that the overdistended kidney pelvis could most directly and easily be accessed with the patient in the prone position.

In 1976 Ferstrom and Johannson extracted the first kidney stone after multiple dilation sessions of a percutaneous tract [3]. A few years later, Karamcheti and O'Donell [4], Smith *et al*. [5], Wickham and Kellet [6], Alken [7], and other urologists learned and perfected the percutaneous nephrolithotomy (PCNL) technique, but not the puncture procedure. They continued to follow the primitive advice of radiologists.

In the late 1980s, after having performed some corpse dissections and computer axial computed tomography (CT) checks, we described PCNL with the patient in the supine position, and the multiple advantages of this position for endourologic surgery [8, 9] (Figure 10.1). We demonstrated out technique, sometimes using live surgery, at many international congresses, meetings, and courses, convincing a few urologists to adopt this approach. In the *Journal of Endourology* we asked the question, “Why is percutaneous nephroscopy still performed with the patient prone?” [10], and showed a radiologic intraoperative image of simultaneous access to the kidney (transureteral and percutaneous) with rigid instruments, but still this did not recruit more followers. It was only by the time of our article in the *Journal of Urology* in 1998 [11] that this position had become more widely used internationally, but use was still limited in the USA.

Today PCNL in the supine position has attracted much interest, and the number of urologists who recognize its multiple advantages is increasing.

Supine positioning

It is advisable that the surgical table is radiolucent, with articulated leg supports; thus, the patient can lie in a pure supine position or with their legs separated and flexed. In both cases, a 3-L water or air bag is situated under the lumbar fossa of the target kidney (Figure 10.2; see Video 10.1) It is important that the edge of the bag and the patient's flank are alongside the surgical table edge, in order to facilitate the free movement of the nephroscope (see Video 10.1). Some nephroscopes are short (<20 cm) and are not recommended, as they receive light and water connections from opposite sides, which causes problems for the positioning of bag or the patient's hip, and obstructs the tilting movements of the endoscope.

The patient's legs may be extended (with their feet oriented upwards or slightly obliquely) (Figure 10.3), or flexed on leg supports. If the latter, we prefer to set the contralateral leg lower to facilitate the ureteral access with a rigid ureterorenoscope (Figure 10.4). (see Video 10.1). The ipsilateral arm of the patient is flexed and fixed onto their thorax with adhesive drape.

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Figure 10.1 Corpse dissection. Two hook separators depress the Toldt line and this ensures that the needle does not touch either the peritoneum or colon.

Figure 10.2 Lumbar fossa is draped over the 3-L sac right at the edge of the table.

Variations

Some modifications of this position have been described. Some urologists prefer to rotate the patient a little more [12]. In this case, the direction of the tract is more horizontal and the entrance skin point is slightly more distant from the 3-L bag.

Some urologists prefer to maintain the oblique position of the patient by means of two bags or gel pads, one underneath the shoulder and the other underneath the hip. In their opinion, this procedure allows for larger nephroscope movements [13].

Others prefer the pure supine position, without any element of suspension under the lumbar fossa [14–16]. In these cases it is preferable to use a special surgical table, without any metal bar on its lateral edge. Then, the flank of the patient can be positioned at the table edge and freedom of movements is maximized.

Finally, others prefer to position the patient with their legs flexed on supports, but with the ipsilateral leg lower and more extended [17].

As we have described previously [10, 11], when we have needed to perform PCNL with simultaneous rigid ureterorenoscopy (URS) , we position the patient with their legs flexed in supports, with the ipsilateral leg more elevated and the contralateral more descended, because we consider this position to be more physiologic with less force on the patient's waist. In the early years of the rigid URS, Pérez-Castro and Martinez-Piñeiro [18] described how it was easier to work with the patient's legs in this position, without any interference. Futhermore, today with the video camera attached at the ureterorenoscope optic, no force needs to be applied to the patient's legs in this position.

When we consider it will not be necessary to perform a rigid URS simultaneously with PCNL, we prefer to position the patient with their legs extended. In this position it is also possible to perform ureteral catheterization or URS with a flexible instrument. However, as ureterenoscopes are actually semi-rigid and very thin, we more frequently use simultaneous access.

Puncture technique

With the patient in the supine position it is easy to explore the kidney with an ultrasound 3.5-MHz probe and calculate the direction in which the needle must be inserted. Futhermore, if the ultrasound probe has a puncture channel, it is possible to use ultrasonography to guide initial access. Nevertheless, this requirement is not necessary and we almost never use it.

With this technique it is possible to puncture the calyceal papilla without having to rotate the C-arm fluoroscope. Initially we superimpose a long metal instrument (e.g. a nephroscope or stone grasper) on the patient's abdomen and under fluoroscopic control place its distal tip over the selected calyx (Figure 10.5; see Video,10.1). Then we mark this point on the sterile drape as it indicates the orientation of the needle. With this maneuver we also know where the skin entry point will be situated (between the 12th rib and iliac crest). If necessary, the puncture can also be between the 11th and 12th ribs (Figure 10.6).

The skin entry point must be situated one or two fingers above the 3-L bag. This point is always behind the posterior axillary line (see Video 10.1). For those performing their first cases, it is advisable to draw the

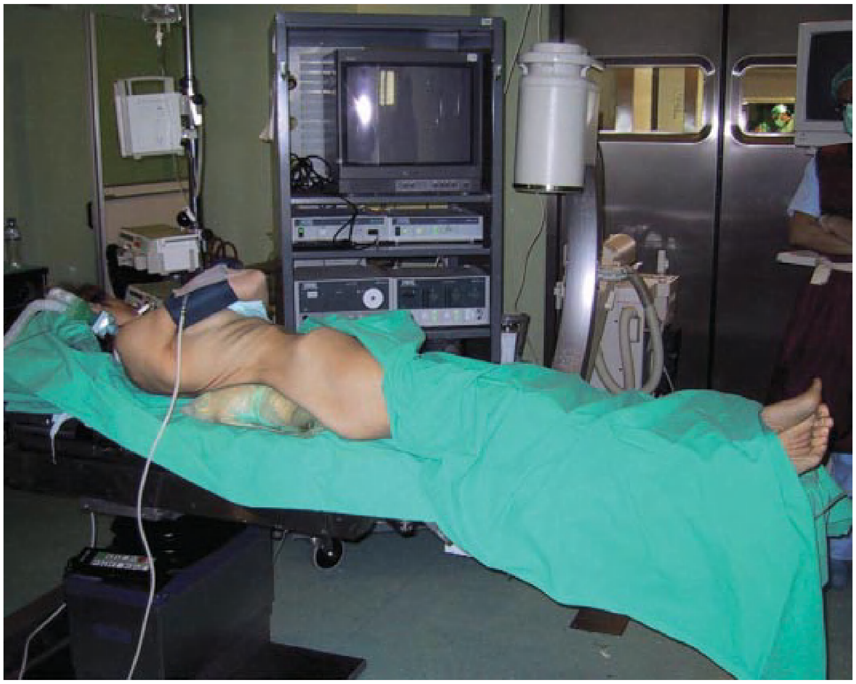

Figure 10.3 Patient's legs are completely extended. Note that her feet are not in a lateral position.

Figure 10.4 Mixed position. Patient's legs are flexed on supports, but with the contralateral leg lower to facilitate ureteral access using a rigid ureterorenoscope.

axillary line on the patient's skin when they are either sitting or standing up, with their arms extended and hanging down. If the line is drawn when the patient is already lying down on the surgical table with the 3-L bag under their lumbar fossa and their arms crossed and flexed over the chest, the position of the line will appear too far forwards.

After having crossed the skin and muscular layers with the needle in an ascending direction (see Video 10.1, we wait for the moment when the selected calyx is well distended with contrast, and then palpate the renal capsule with the tip of the needle. If we have a good response from the kidney (i.e. backward movement and in some cases distortion of the calyceal cup), we advance

Figure 10.5 A nephroscope stone grasper is superimposedon the patient's abdomen and fluoroscopy is used to guide the positioning of its distal tip over the selected calyx.

Figure 10.6 Finger pointing to the previously marked point in the sterile drape. The needle penetrates the skin over the serum sac, two finger breadths away from the marked point, and is then directed in an ascending direction to this point.

the needle and penetrate the calyx. If not, it is necessary to retract the needle from the kidney and try and palpate it again in a higher or lower direction (see Video 10.1).

In some cases, when puncture fails, before extracting the needle, it is possible to move the needle upwards or downwards under fluoroscopic guidance. If the contrast filling the calyx is displaced when the proximal tip of the needle is manipulated, it is because the needle is situated underneath the calyx and its tip is compressing the calyx. In this situation, the needle must be extracted from the parenchyma, and a new attempt at puncture made, but this time directing the needle's tip higher. Incorrect punctures are usually due to the fact that the puncture is in a horizontal instead of in an ascending direction.

When the selected calyx has been reached and the first urine drops are obtained through the needle, the guidewire is introduced and the tract can be dilated, initially by means of a thin flexible Teflon dilator and then with the Alken telescope set or a balloon dilator set (see Video 10.1).

With these few tricks it is possible to puncture the selected calyx without having to make complex angle calculations while rotating the C-arm fluoroscope.

Advantages of the supine position

Supine access is more comfortable and safer for the urologist, because they can work in a sitting position and their hands are never in reach of the X-ray.

Calyceal puncture is easier than when the patient is in the prone position. With the supine position, the incidence of the X-ray is perpendicular to the needle and calyx axis, and displacements of the calyceal papilla are better appreciated when the tip of the needle is pushing in front of them, making it unnecessary to rotate the C-arm fluoroscope (see Video, 10.1 another example; puncture 3).

There are no iatrogenic risks, because it is not necessary to change the position of the patient, in whom an endotracheal tube, urethral sound, ureteral and intravenous catheters, some electrodes, etc., will have been inserted, and time is not expended on this maneuver.

In the pure supine position, it is possible to insert a ureteral catheter by means of a flexible endoscope.

In the supine position, intervention is better tolerated by high-risk patients, especially the old and obese, because the vena cava is not compressed and the diaphragm is not pulled up. Moreover, in obese patients, the fat apron displaces towards the contralateral side, thus reducing the distance from the skin to the kidney.

All patients will be more comfortable in the supine position. In certain cases, it is possible to perform PCNL with regional or even local anesthesia, complemented by intravenous sedation. In the event of any complication, the supine position will mean the anesthesiologist can introduce without problem an endotracheal tube and continue with a general anesthesia.

In the supine position, the risk of puncturing the colon is less than in the prone position, because when the 3-L bag elevates the lumbar fossa, the kidney and the colon are elevated too. In the prone position, the colon is pulled back, increasing this risk of damage.

One of the best technical advantages of the supine position is the ability to perform simultaneously PCNL and URS. With the two endoscopes inside the kidney it is easier to find, fragment, remove, and deliver the stone fragments to be extracted through the Amplatz sheath (see Video 10.1).

Other advantages stem from the ascending direction of the tract. This helps maintain a low intrarenal pressure, making the technique more secure and easier, because the stone fragments are dragged out by the whirlpool of water created in front of the optic, and auxillary instruments are not needed for their extraction (see Video 10.1).

Disadvantages

The supine position has a few disadvantages. In this position there is usually a delay in the filling of the inferior calyces with the contrast, because the inferior renal pole is more elevated than the superior one. This inconvenience can be overcome by positioning the patient, for a few minutes, in an anti-Trendelemburg position.

For percutaneous intervention, distention of the collecting system will be greater in the prone than in the supine position. However, if needed, greater distention in the supine position can be achieved with a simple gauze knot tied around the nephroscope tube, like a plug at the proximal end of the Amplatz sheath. Also, limited filling of the pyelocalyceal system has two advantages: first, it guarantees low intrarenal pressure, and second, in some cases, it reduces the time that it is necessary to work with water [14].

In some thin patients with renal ptosis, the kidney can be hypermobile in the supine position. This inconvenience is overcome by fixing the kidney during tract establishment by means of contralateral abdominal compression.

In some patients with wide hips and thin calyces, it can be more difficult or impossible in the supine position to reach the upper calyx with a rigid nephroscope (see Video 10.1). This difficulty can be solved by performing simultaneously a URS, or by using a flexible nephroscope (see Video 10.1).

Some authors who prefer to make access through the upper calyx have indicated that in the supine position this is more medial and posterior, making access to the upper pole difficult [15]. Nevertheless, others have not been inconvenienced making this upper pole access with their patient in the supine position [16].

Conclusions

Establishing good percutaneous renal access is a crucial step in the PCNL technique. In the supine position, renal access is a simple and safe method which is at reach of any urologist, without the support of any other specialist.

In the supine position, the kidney can be easily explored with ultrasound and punctured with a fluoroscopic C-arm in a fixed position. Biplanar fluoroscopy with a rotating C-arm is no longer essential.

The supine position facilitates the procedure: the urologist can be sitting, with their hands always outside the reach of X-ray. There is also the enormous advantage of being able to combine simultaneously PCNL with a rigid URS, if necessary.

With the supine approach, patients (especially those who are obese) have physiologic intra-abdominal pressures, and therefore less risk of cardiorespiratory complications. In addition, the risk of iatrogenic events is minor, because the position of the patient does not need to change during the intervention.

Our best advice is to try supine positioning, at least once.

CHAPTER 11

Prone, Lateral, and Flexed: Patient Positioning for Percutaneous Nephrolithotomy

A. Andrew Ray & R. John D'A. Honey

Division of Urology, Department of Surgery, St. Michael's Hospital, University of Toronto, Toronto, Canada

Introduction

Positioning for percutaneous nephrolithotomy (PCNL) is an important, yet often neglected, aspect of the procedure. Operators invariably become wedded to one position, yet with knowledge and experience of other positions, there is the freedom to choose the most appropriate technique for the case at hand. Since the introduction of percutaneous renal surgery for stone disease by Fernstrom and Johansson in 1976 [1], there has been a proliferation of case series addressing various modifications to patient positioning, including the lateral decubitus position [2–4], modified lateral [5], reverse lithotomy [6], split-leg [7, 8], and supine [9]; however, most of these have not gained widespread acceptance. Today, PCNL is usually performed with the patient in the prone position. We have recently described a prone–flexed modification that confers several advantages over the conventional technique [10].

In this chapter, we review in detail both the conventional prone technique as well as our prone–flexed modification. Additionally, we describe the lateral and our lateral–flexed technique, which we find particularly useful in morbidly obese patients and those with severe kyphoscoliosis. We have also attempted to provide an anatomic explanation for the known complications associated with PCNL, and how attention to patient positioning can mitigate these issues. Finally, the rare complications related to patient positioning are discussed in detail.

Prone and prone–flexed positions

Due to the retroperitoneal location of the kidneys and their proximity to the flank, PCNL is most commonly performed in the prone position with straightforward access to the collecting system. However, when the procedure was being developed in the early 1980s, direct calyceal puncture was not thought to be important, provided that puncture was along the avascular line of Brodel. It has since been recognized that puncture directly into a calyx provides the safest access for stone removal [11, 12]. At present, the majority of PCNLs are performed with the patient prone and access is obtained through a posterior or posterolateral calyx. This position confers numerous advantages, with the main disadvantages being the time required for patient repositioning and anesthetic concerns in the morbidly obese (Table 11.1). We have previously shown that the prone–flexed position, a simple modification to conventional prone positioning, has several additional advantages [10] and can be implemented on most operating room (OR) tables.

Percutaneous lithotomy in the prone and prone–flexed positions (see Video 11.1)

Retrograde pyelogram and choice of calyx

To perform fluoroscopically-guided access, a high-quality retrograde pyelogram is essential. Consequently, we begin all procedures with the patient positioned supine. Once the patient has been intubated under

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Table 11.1 Options for prone patient positioning.

	Technique	Advantages	Disadvantages
Prone	Patient is prone with a padded role under the thorax to facilitate ventilation	Large field with wide choice of calyces for access Easy end-on access to the posterior calyces Easiest access to upper pole Wide space for instrument manipulation Renal pelvis is dependent with easier access to mobile stones Optimal position for fluoroscopically guided access ("bullseye" or "triangulation") Minimal interference from the OR table	Patient repositioning prolongs OR time Difficult in obese patients Risk of respiratory or cardiovascular compromise Theoretical risk of ocular complications
Prone-flexed	Patient is prone, with a padded role under the thorax to facilitate ventilation Flexed at the waist 30–40° Knees are flexed 15°	Similar advantages to prone position Further increased working space Flattened flank decreases instrument conflicts with buttock May convert supra-11th to supra-12th or supra-12th to infracostal access	Similar disadvantages to prone position Extra padding needed due to head-down position May increase airway pressures
Prone split-leg	Patient prone, with the genitalia at the bottom of the OR table Legs on padded adaptors and abducted up to 45°	Similar advantages to prone position May perform ureteroscopy without patient repositioning or fear of contaminating instruments	Similar disadvantages to prone position Patient is further down the OR table, away from the anesthesiologist

general anesthesia, flexible cystoscopy is performed. In men, this is performed with the patient supine, while the frog-leg position is useful in women. A 5F Flextip (Cook Medical) ureteral catheter with a terminal side hole, which facilitates aspiration, is passed into the collecting system. Urine is completely aspirated and replaced with radiographic contrast to identify all calyces. Urine is less dense than contrast. As a result, any urine within the collecting system will tend to collect at the highest point within the kidney. This property can be helpful to the surgeon when distinguishing anterior and posterior calyces. In the supine position, posterior calyces are identified by the presence of denser contrast within them, while anterior calyces appear paler due to the mixture of contrast with urine. In contrast, when the patient is repositioned prone, posterior calyces will appear paler. If too much pure urine without contrast is present, these calyces may be poorly visualized or even invisible.

A C-arm image intensifier is used to examine the anatomy of the collecting system and the position of all stones. Four fluoroscopic images are captured: a scout image to identify all calculi, an anteroposterior, and two obliques. These images help create a mental three-dimensional (3D) picture of the calyceal anatomy, and can be referred to during the procedure. In the anterolateral view, the posterior calyces are viewed from the side and appear longer, whereas in the anteromedial view, they are seen through the central axis of the kidney and are viewed end-on, appearing shorter (Figure 11.1).

A ureteral occlusion balloon is then inserted over a guidewire, positioned at the uteropelvic junction (UPJ), and secured externally to a Foley catheter. A three-way valve is attached and connected to a 10 mL syringe and intravenous tubing leading to a bottle of contrast. This allows aspiration and infusion of additional contrast as needed during the case. Using an occlusion balloon has several benefits. First, the balloon prevents stone fragments from falling into the ureter. Second, the constant pressure of contrast in the renal collecting system ensures a persistent pyelogram, facilitating calyx identification when the patient is repositioned prone. Third, flow of contrast under gravity distends the collecting system, providing a larger target for access. Fourth, free return of contrast out through the needle allows the surgeon to rapidly confirm successful puncture of the chosen calyx. Finally, the occlusion balloon can act as a safety device, providing control of the ureter and UPJ throughout the procedure.

Renal puncture and dilation of the tract

With a Foley catheter *in situ* and the ureteral occlusion balloon secured externally, we reposition the patient

Figure 11.1 3D model of the lower pole renal collecting system of the right kidney with the patient in supine position. The posterior calyx is dependent, filling with dense contrast. Anterior calyces are paler due to the mixture of contrast with less dense urine. (A) With the C-arm rotated 30° toward the left side of the patient, the posterior calyx is viewed end-on and appears shorter. (B) Anteroposterior view. (C) With the C-arm rotated 30° toward the right side of the patient, the posterior calyx is viewed from the side and appears longer (reproduced from Ray *et al*. [10] with permission.

prone with the assistance of additional staff members. Generous padding is placed under the knees, feet, and chest to prevent pressure injury and to facilitate ventilation (Figure 11.2). Our anesthesiologists use generous padding of the eyes to prevent corneal abrasions and have various head supports at the ready with cut-out holes for the endotracheal tube. We have found that there is no one support that is universally appropriate for all patients, so several options are available at all times. To prevent brachial plexus injury, the shoulders should be situated below the chest and are both externally rotated at the shoulder and flexed at the elbow. Again, generous padding is utilized. Finally, a safety strap is place across the buttocks.

In the prone position, the natural, anterior lordosis of the spine is exaggerated. This complicates access by compressing the working space and leads to instrument conflicts with the buttocks. To avoid this, the table can be flexed 30–40° to open the space between the 12th rib and the posterior iliac crest (Figure 11.3). Flexion of the hips not only increases the working space on the patient's flank, but also may rotate the ribs cephalad, further increasing the working space and possibly converting a supracostal to an infracostal access.

Skin preparation is up to the surgeon's preference. In one recent multicentered randomized study examining the issue of surgical site infections following clean-contaminated surgery, it was found that skin preparation with chlorhexidine–alcohol was superior to povidone–iodine in the perioperative period [13]. We perform wide skin preparation from above the 10th rib to the buttocks and from the spinous process in the patient's midline, laterally to the mid-axillary line. Due to the copious amount of irrigation necessary for PCNL, we use an adhesive neurosurgical drape with a drainage pouch connected to suction to direct fluid away from the patient. Only normal saline irrigation is used unless electrocautery is required, when it is changed to a nonelectrolyte solution such as is used for transurethral prostatectomy. To prevent hypothermia, all irrigation fluid is heated to 42°C in a warming cabinet.

"Bullseye" technique

The C-arm is draped and used to identify the previously chosen calyx. Due to the change to the prone position, the posterior calyces are now less dense as the heavier contrast flows anteriorly (Figure 11.4). We favor a conventional "bullseye" technique for performing renal puncture in the prone position; however, a "triangulation" technique can also be used (described below). Prone and prone–flexed positioning allows maximal

Figure 11.2 Configuration of OR table with padding and C-arm.

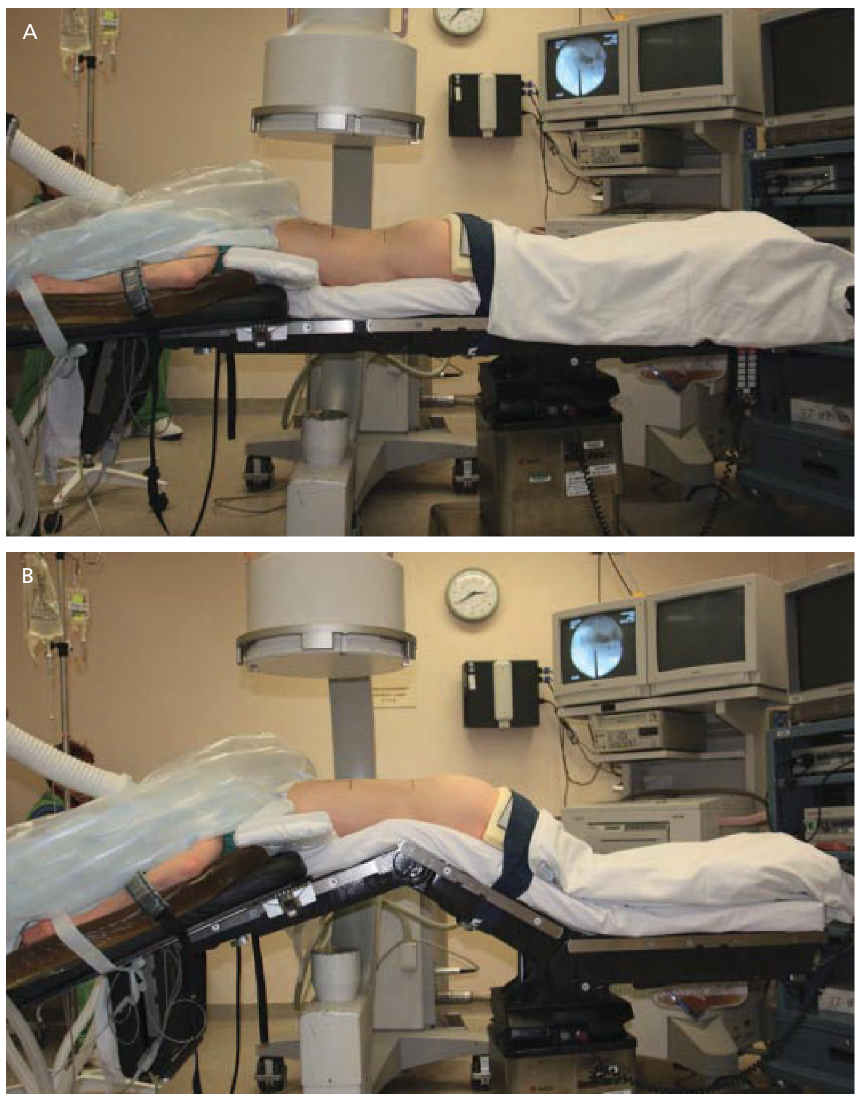

Figure 11.3 (A) Prone and (B) prone-flexed patient positions. A padded support is placed under the patient's chest to improve respiration. With the OR table flexed 30–40°, the patient's flank is flattened and there is increased area available for puncture. Note also that prone–flexed positioning decreases obstruction from the buttocks with lower pole access.

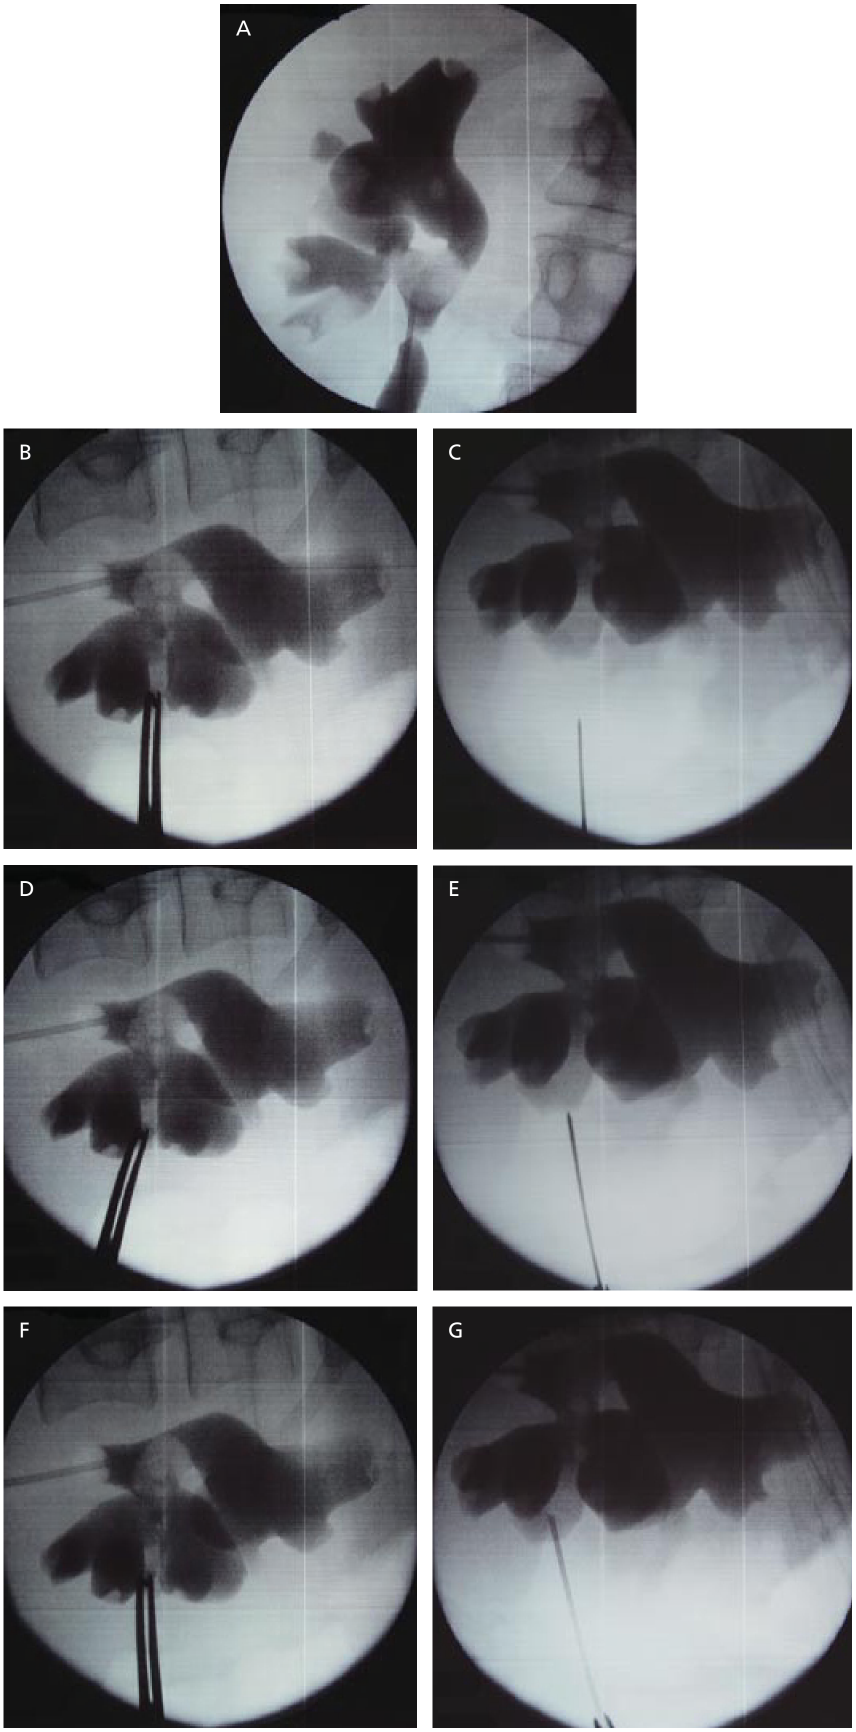

Figure 11.4 "Bullseye" technique. (A) Anteroposterior (AP) view with the patient in the supine position. All subsequent images are with the patient in the prone–flexed position. (B) AP view with the forceps holding the needle and aimed at the chosen posterior calyx. (C) 30° oblique view demonstrating the depth required for puncture. (D) AP "bullseye" view. (E) 30° oblique view. (F) AP view. (G) Oblique view with the chosen calyx successfully puncture by the needle.

excursion of the C-arm around the OR table, giving the widest possible unobstructed imaging windows. In the prone position, the posterior calyces move in the opposite direction to the image intensifier of the C-arm (Figure 11.4). With the C-arm rotated 30° from the vertical, towards the operator, the posterior calyces move away, and shorten. In this position, the calyx of choice is viewed end-on. We use an 18G Trocar needle to puncture the calyx in the center of the papilla. This needle lacks a beveled edge and as such, resists deflection away from the axis of puncture. The needle is inserted and advanced along the line of the X-ray beam. To assess the depth of the needle, the C-arm is periodically rotated away from the operator (Figure 11.4). To minimize radiation exposure to the surgeon's hands, the needle can be held in a long Kelly forceps, aligned with the calyx under fluoroscopy, and advanced during expiration without fluoroscopy. Once the calyx is entered, and a free flow of contrast obtained, an Amplatz extra-stiff or super-stiff guidewire is passed down the needle into the collecting system. Due to the presence of the occlusion balloon, we do not attempt to pass the guidewire down the ureter, although this may occur. A small depth gauge ring on the needle is adjusted to skin level to mark the depth between the skin and the collecting system. Knowledge of this measurement reduces radiation exposure during insertion of the fascial dilators and nephrostomy tract dilating balloon. Initially, thin fascial dilators are used to dilate the tract to a short 10F, and then a safety guidewire can be inserted using a 10F dual-lumen catheter. The tract is then further dilated to 30F with a nephrostomy tract dilating balloon over which an Amplatz sheath with a 30F inner diameter is passed. Although different methods of tract dilation exist, including balloons, Amplatz serial dilators, and the Alken telescopic dilator among others, we favor balloon dilation. We have found this to be both quick and atraumatic, although this comes at increased cost.

Adjuncts to assist with patient positioning

The prone–flexed modification can add several advantages to the operating surgeon without any impediment to C-arm movement. Adopting this position on an OR table without a flex-option is still possible through the use of bolsters. The "Montreal mattress" is a preshaped surgical bolster that can be used as an adjunct for the support of prone patients [14]. The advantage of this device is the central cavity which allows for free movement of the abdomen. Theoretically, this should lessen respiratory compromise and minimize cardiovascular effects such as inferior vena cava (IVC) obstruction. Another option is the radiolucent Wilson frame, an adjunct used by spinal surgeons to mimic the prone–flexed position on a standard OR table. Its advantages include the ability to control the degree of flexion required as well as to use adjustable contour pads that allow for free excursion of the abdomen, preventing respiratory compromise. The main limitation to its use is the reduction in depth, preventing C-arm movement, instrument manipulation, with fluoroscopic guidance.

Advantages and disadvantages of the prone position

As mentioned, the majority of PCNLs are still carried out with the patient in the prone position, with prior retrograde placement of a ureteral catheter or occlusion balloon under fluoroscopic control. This initial procedure can be performed with the patient either supine or prone. If performed while the patient is supine, it is necessary to position and drape the patient twice, prolonging OR time [15, 16]. By commencing the procedure with the patient in the prone position immediately following induction of general anesthesia, the patient will still require repositioning, but is only draped once [17]. A split-leg modification can facilitate access to the external genitalia, for simultaneous antegrade and retrograde approaches [7, 8]. In the prone position it may be difficult to access the anteriorly displaced ureteric orifices for the retrograde study, but with practice this can become routine. Additionally, if the procedure is started prone, identification of the posterior calyces, especially in obstructed systems, may be difficult, or impossible, as the presence of pure urine within the collecting system may float on top of the radiographic contrast and render them invisible. For this reason, it is our preference to begin the procedure with the patient supine.

Prone positioning for PCNL allows access to the entire flank, with a wide choice of access sites, especially when multiple accesses are required. Although still possible in the supine position, upper pole access is significantly easier when the patient is prone. An upper pole puncture has many advantages, including the ability to work down the renal axis, with minimal torque, as the more mobile lower pole rotates to align with the nephroscope. This reduces the chance of renal parenchymal shear and bleeding. Selection of an upper pole calyx is indicated in obese patients, as the upper pole is closer to the posterior abdominal wall than the lower pole. It is also indicated in patients with staghorn calculi, or stones in a horseshoe kidney, and facilitates access to multiple lower pole calyces, with a single tract. In contrast, from the lower pole, visualization of the upper calyces with a rigid nephroscope is rarely possible. Finally, dilation into the upper pole is easier, due to more adherent attachments to Gerota's fascia limiting renal mobility, whereas the more mobile lower pole may move away

from the operator during dilation and kink the guidewire. Despite these advantages, many authors still prefer a lower pole puncture with the reassurance that this approach will avoid thoracic complications.

The prone–flexed modification that we describe provides several additional advantages over the traditional technique. First, and most obviously, the working space is further increased. In addition, we have shown that when in this position, the kidneys are displaced inferiorly in the retroperitoneum. This effect is most pronounced with the left kidney, which is lower than the right kidney in greater than 90% of cases. Also, due to this modification, a supra-11th rib access may be converted to a supra-12th rib, or a supra-12th to an infracostal access. Finally, the flank is significantly flattened, eliminating interference from the buttock during rigid nephroscopy through a lower pole tract [10].

Lateral and lateral–flexed positions

Although the prone–flexed position for PCNL can be used for the obese patient, the lateral position has multiple advantages in these patients, and is sometimes the only feasible position for the morbidly obese patient with a body mass index in excess of 50 kg/m^2 who cannot be ventilated prone. This position allows the protuberant abdomen and pannus to fall laterally, taking the weight off the anterior abdominal wall as occurs when the patient is supine (Figure 11.5). This maximizes diaphragmatic excursion and facilitates general anesthesia. The pannus can also be supported separately if required.

The lateral–flexed position is familiar to any urologist who performs open and laparoscopic renal surgery. This position significantly widens the space between the 12th

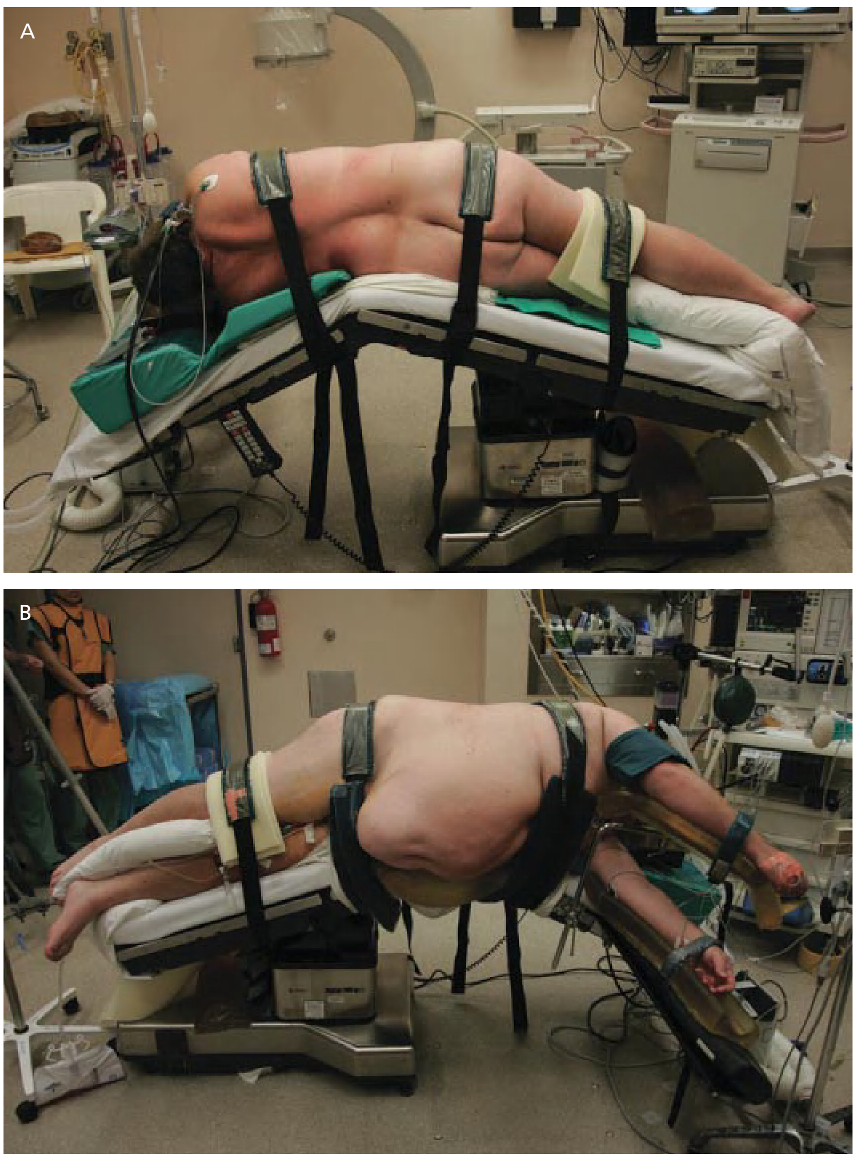

Figure 11.5 Lateral-flexed patient position. (A) Posterior view. A wedge with a groove for the dependent arm is placed under the patient's torso. (B) Anterior view. Both arms are supported and flexed slightly at the elbow. Generous padding is used to prevent injury. Note that the pannus falls away from the patient, preventing respiratory compromise.

rib and the iliac crest, flattening the folds of adipose tissue and facilitating percutaneous access (Figure 11.6). The increased distance between the 12th rib and iliac crest, produced by this flexion, is even more pronounced than the increase produced by flexion with the patient prone. Also, in this position, the relative lack of adipose tissue over the costovertebral angel is frequently surprising in these morbidly obese patients and, provided the upper pole calyx is chosen for access, it is frequently possible to use a standard length Amplatz sheath and nephroscope.

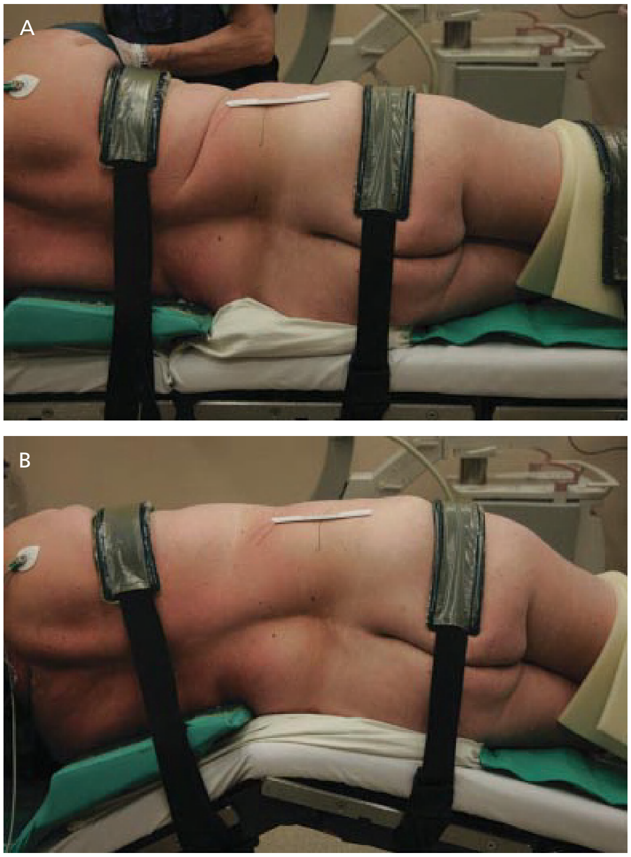

Figure 11.6 (A) Lateral and (B) lateral-flexed patient positions. As with prone-flexed positioning, when the OR table is flexed 30–40°, the patient's flank is flattened and there is increased area available for puncture.

One disadvantage to flank positioning is that percutaneous access usually requires either ultrasound guidance or use of "triangulation" using the C-arm image intensifier, as opposed to the "bullseye" technique. This is partly because of the restricted arc of rotation of most C-arms, but also because the metal side rails of most radiolucent tables prevent adequate visualization of the collecting system when the C-arm is rotated to an exaggerated position. Advantages of the lateral and lateral–flexed positions are outlined in Table 11.2.

Percutaneous nephrolithotomy in the lateral and lateral–flexed positions (see Video 11.2)

As with prone or prone–flexed PCNL, the procedure begins with a retrograde pyelogram and insertion of a ureteral occlusion balloon. This is performed with the patient supine in order to choose the most appropriate calyx, as described earlier (Figure 11.7).

In the lateral–flexed position the arms and legs are positioned as for open or laparoscopic renal surgery, and the patient is secured to the table with padded straps or tape over the upper chest and pelvis (Figure 11.5). An axillary roll or padded wedge with a groove to accommodate the dependent arm must be placed to adequately support the chest and prevent positioning-related injury. Extra padding must also be placed under the dependent knee and ankle to prevent pressure-related complications.

The concept of triangulation is illustrated in Figures 11.8 and 11.9. With the C-arm in the anteroposterior configuration, it is possible to determine the

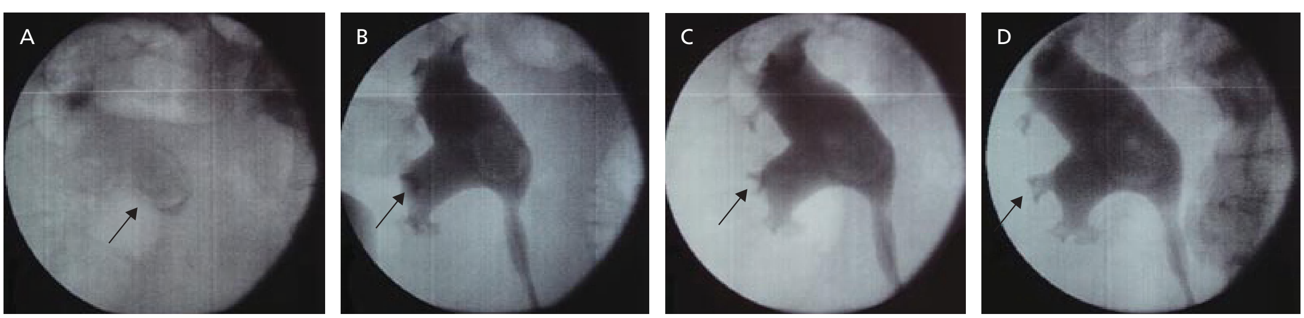

Figure 11.7 Choosing a posterior calyx (arrow) in the lower pole of the right kidney, for the case demonstrated in Figure 11.10. The patient is in the supine position and the posterior calyces appear darker. (A) Renal pelvic stone. (B) Oblique view with C-arm rotated 30° toward the left side of the patient, making the posterior calyx appear shorter. (C) Anteroposterior view. (D) Oblique view with the C-arm rotated 30° toward the right side of the patient, making the posterior calyx appear longer.

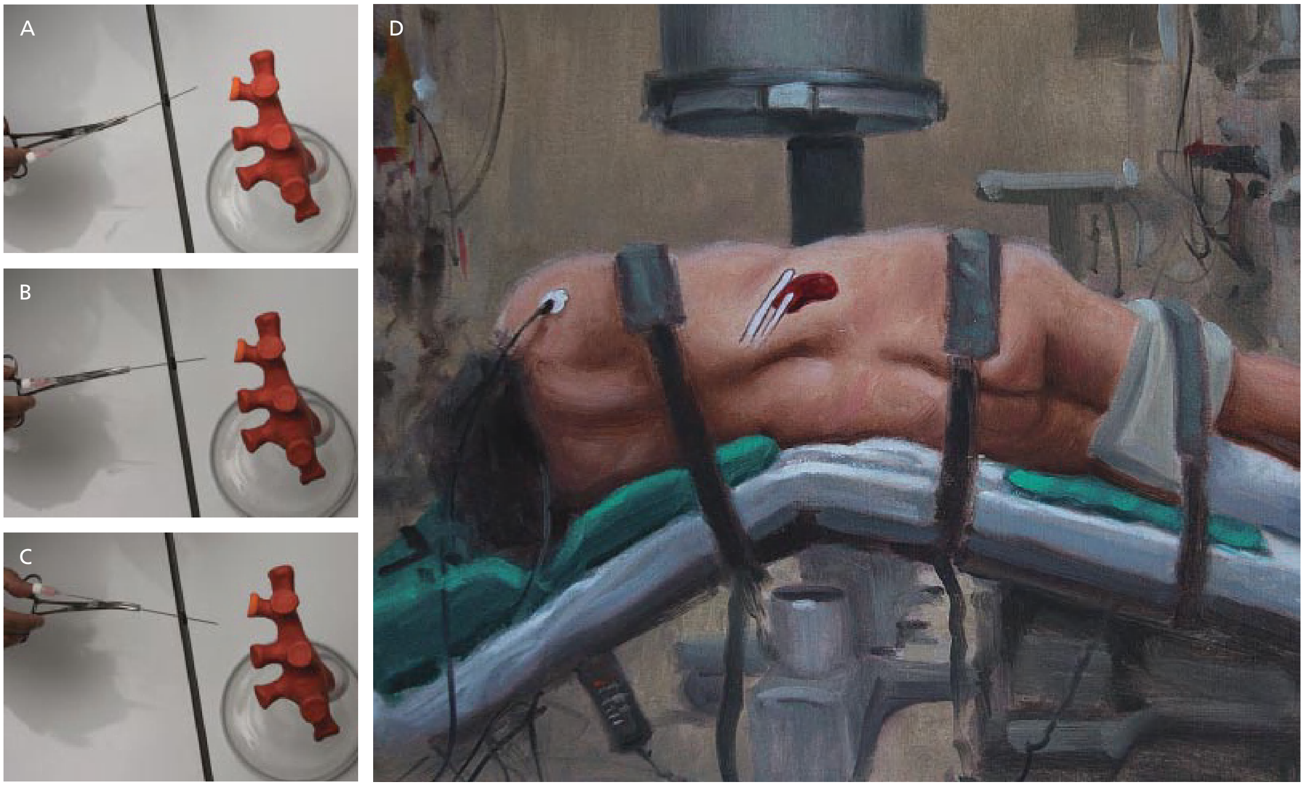

Figure 11.8 Anteroposterior views with the patient in the lateral-flexed position. In this demonstration, the target is an upper pole, posterior calyx, viewed from directly above. The chosen calyx is seen from the side, facing posteriorly. (A) Needle is aiming too cephalad to the target calyx. (B) Needle will have direct entry into the papilla of the desired calyx. (C) Needle is aiming too caudal to the target. (D) Illustration depicting the position of the C-arm necessary to obtain this view.

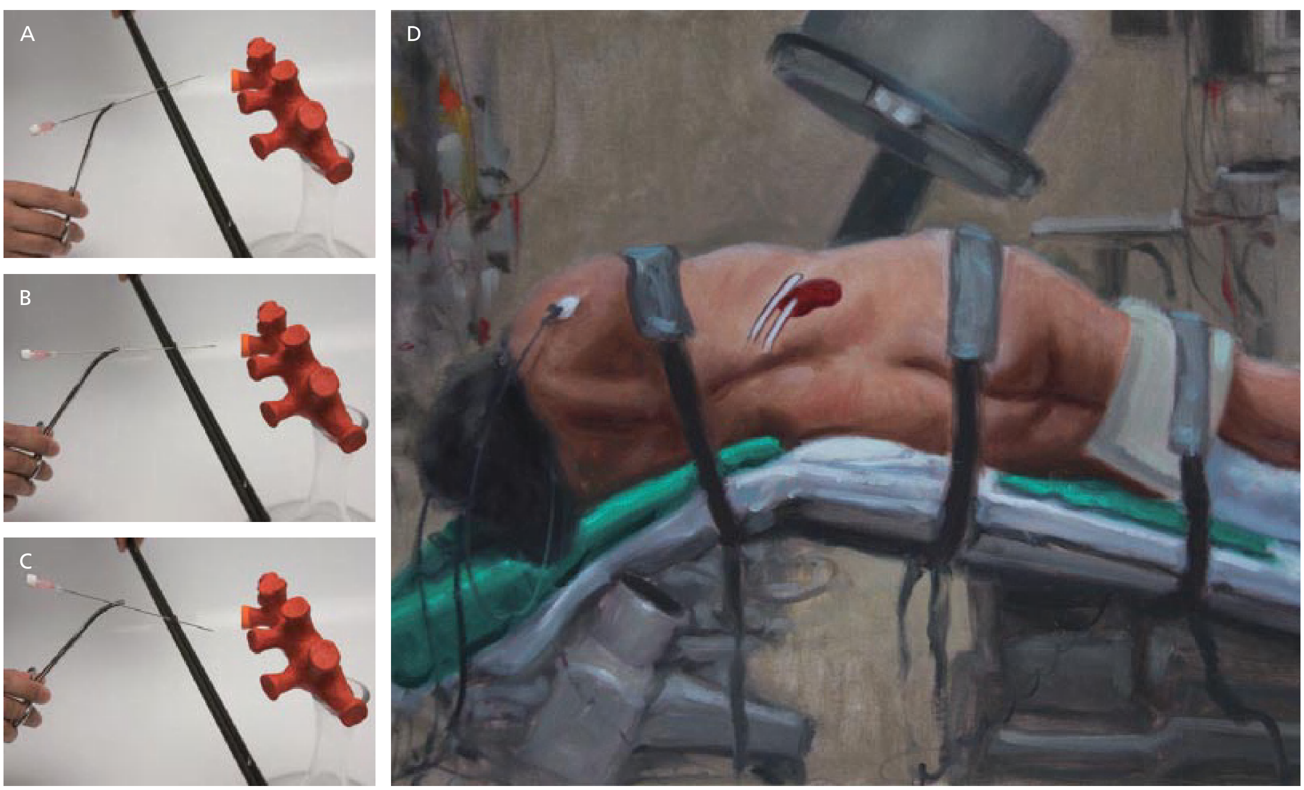

Figure 11.9 Oblique views with the patient in the lateral–flexed position. With the C-arm offset approximately 30° towards the feet, the targeted posterior, upper pole calyx is identified. (A) Needle is aiming too far anterior to the target calyx. (B) Needle will have direct entry into the papilla of the desired calyx. (C) Needle is aiming too far posterior to the target. (D) Illustration depicting the position of the C-arm necessary to obtain this view.

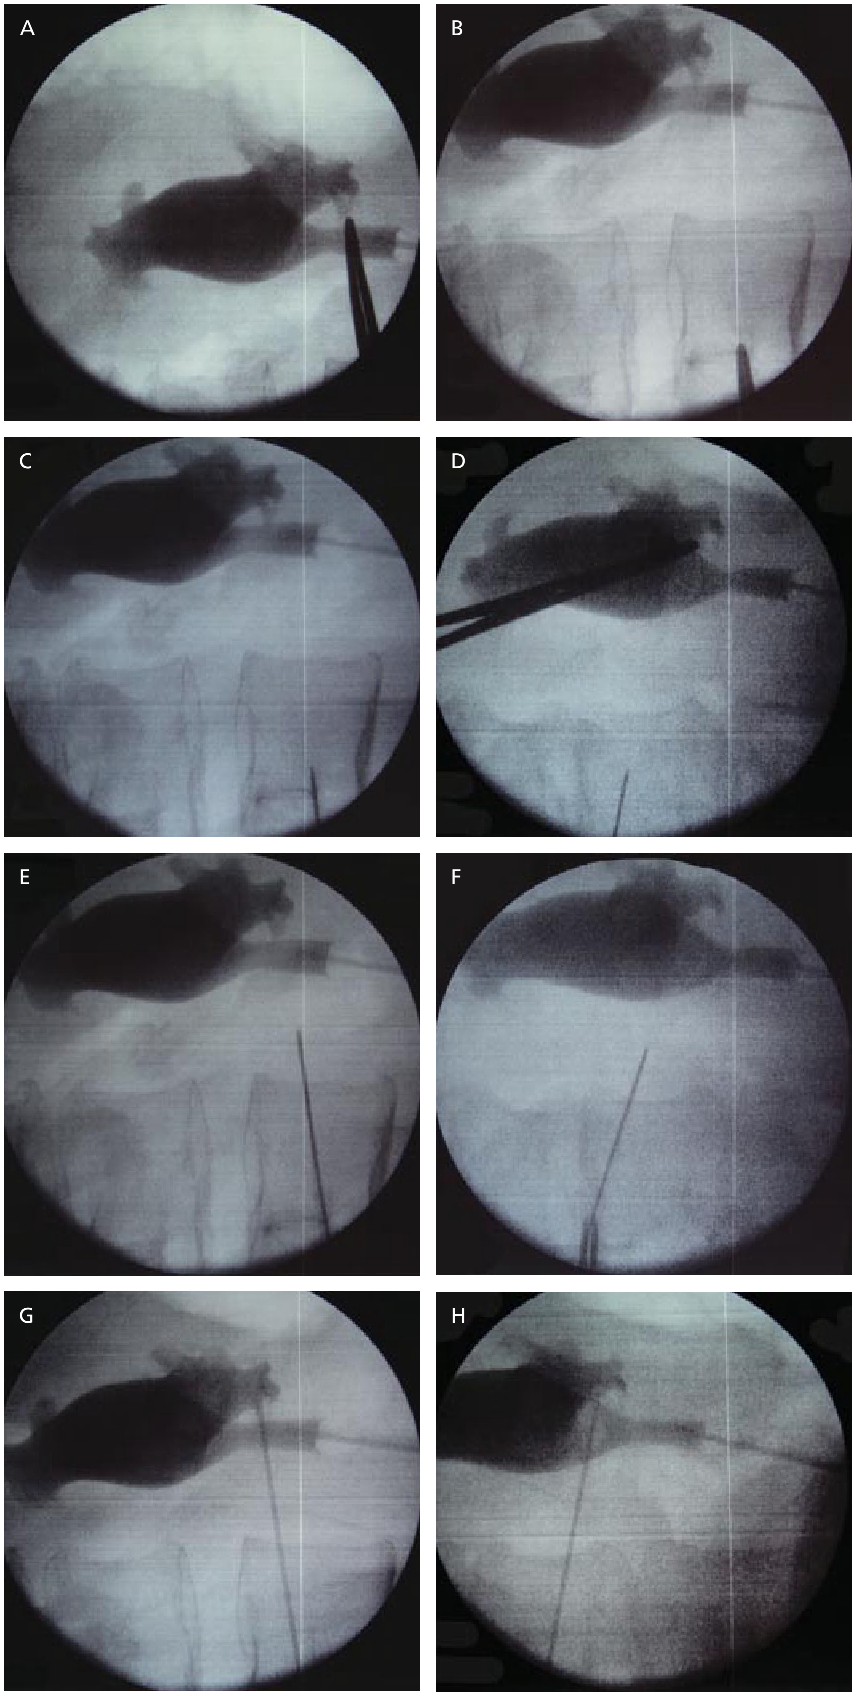

Figure 11.10 Triangulation technique with an obese patient in the lateral-flexed position. (A) Forceps pointing to chosen posterior calyx viewed in anteroposterior (AP) direction. (B) Point of entry chosen with forceps marking point lateral to the paraspinal muscles in line with the targeted calyx. (C) AP view with the needle along the chosen path. (D) Oblique view with the needle pointing to the chosen calyx. (E) AP view with the needle approaching the calyx. (F) Oblique view with the needle on target, approaching the calyx. (G) AP view with the needle in the chosen calyx. (H) Oblique view with the needle in the chosen calyx.

Table 11.2 Options for lateral patient positioning.

	Technique	Advantages	Disadvantages
Lateral	Patient in lateral decubitus with no break in the OR table	Familiar to urologists who perform open renal surgery Compared with prone, easier patient repositioning from supine Easiest identification of the posterior calyces Useful in morbid obesity or severe kyphoscoliosis Least effect on cardiac and respiratory function Renal pelvis is dependent with easier access to mobile stones More ergonomic for the surgeon than prone position May perform nephroscopy and ureteroscopy simultaneously	Patient repositioning is required Fluoroscopy is technically limited necessitating "triangulation" or ultrasound-guided access
Lateral-flexed	Patient in lateral decubitus with 30–40° break in the OR table	Similar advantages to lateral position Significantly increased working space Reduces flank fat in morbidly obese patients May elevate the lower ribs, reducing the need for supracostal access	Similar disadvantages to lateral position
Modified lateral "Barts technique"	Patient in lithotomy with ipsilateral pelvis elevated 45° Shoulders rotated to be perpendicular to the OR table Ipsilateral leg is flexed and adducted, contralateral leg is fully abducted	May perform nephroscopy and ureteroscopy without patient repositioning Less cardiovascular and respiratory effects than prone Improved access to flank compared to supine	Requires significant patient mobility Not suitable for patients with musculoskeletal deformities Fluoroscopy is technically limited, as with lateral

cephalad–caudal axis for puncture. Oblique views are similarly used to determine the anteroposterior direction of puncture. In this view, directing the needle laterally toward the anteroaxillary line will target the anterior surface of the kidney, while directing the needle toward the spine will aim it toward the posterior surface.

With the patient in the lateral position and the C-arm image intensifier placed on the abdominal side of the patient, the pelvicalyceal system is initially viewed in the anteroposterior position. The previously chosen calyx can be identified facing posteriorly towards the operator (Figure 11.10). The line of access can then be chosen. This can be the shortest distance, at right angles to the back, or can work along the axis of the kidney, angling up into a lower pole calyx or angled down into an upper calyx. The actual puncture is made two finger breadths lateral to the edge of the paraspinal muscles. If necessary, the site that was initially chosen may be adjusted either cephalad or caudally if a rib is in the line of the needle tract. The needle is then advanced with fluoroscopic monitoring. With the C-arm vertical or rotated 10–20° towards the X-ray machine, to lengthen the calyx, the needle is angled in a caudal or cranial direction to point directly at the calyx (Figure 11.10). Holding this angle steady, the C-arm is swung with the intensifier towards the foot of the table and the anteroposterior direction of the needle adjusted to again point directly at the chosen calyx. The needle is then advanced along this line, checking both angles at regular intervals until the calyx is punctured. The stylette is removed and contrast should flow freely from the needle.

Special situations

Morbid obesity

PCNL in the morbidly obese patient with a BMI greater than 40 kg/m^2 poses a challenge for both the operating surgeon and the anesthesiologist. From a surgical perspective, there are several aspects that must be considered. First, achieving satisfactory X-ray penetration can be problematic with older fluoroscopic units, making targeting difficult. Second, anatomic landmarks are also obscured and can make tract placement difficult. This can be especially problematic for upper pole punctures. Third, the depth of the tract is significantly increased and often requires extra-long instruments, including a sheath and rigid endoscopes. Surprisingly, several authors have independently demonstrated that both stone-free rates and perioperative complications appear to be unaffected when PCNL outcomes are stratified by BMI [18–22]. This was despite the increased complexity of these cases and the poor fluoroscopic image quality obtained when using the C-arm to search for small residual fragments.

In terms of patient positioning, the lateral–flexed position seems ideally suited for this clinical situation, with the benefits explained in detail above (Table 11.2). Other authors have similarly used lateral positioning to overcome these difficulties. Kerbl *et al*. described in detail the use of lateral positioning to successfully treat two patients with a BMI greater than 50 kg/m^2. In these patients, it was noted that the supine position could not be tolerated due to respiratory difficulties [2]. Gofrit *et al*. echoed these concerns and similarly adopt the lateral decubitus position in patients with a BMI greater than 40 kg/m^2 [3]. In contrast, conventional prone positioning has been used by several authors for the morbidly obese, including patients with a BMI well over 50 kg/m^2 [20, 21]. The prone position may still be well-tolerated even at extremes of BMI and may be useful when the weight of the patient is greater than the tolerance of the OR table, requiring the use of two tables in close proximity. Wu *et al*. described a technique of awake endotracheal intubation and prone self-positioning in a patient with a BMI of 51 kg/m^2 [23]. In a large series, El-Assmy *et al*. favored supine positioning for morbidly obese patients, but conceded that prone positioning was necessary in some cases]. Finally, Curtis *et al*. described using the prone position in a patient with a BMI of 55.5 kg/m^2. Their technique was to use a larger skin incision to expose the fascia prior to performing puncture [24]. This technique has the potential for avoiding the need for an extra-long working sheath, but can only be used with the patient in the prone or lateral decubitus positions.

Kyphoscoliosis/musculoskeletal abnormalities

The treatment of patients with severe musculoskeletal abnormalities poses a particular challenge to the surgeon, and PCNL is no exception (Figure 11.11). In these

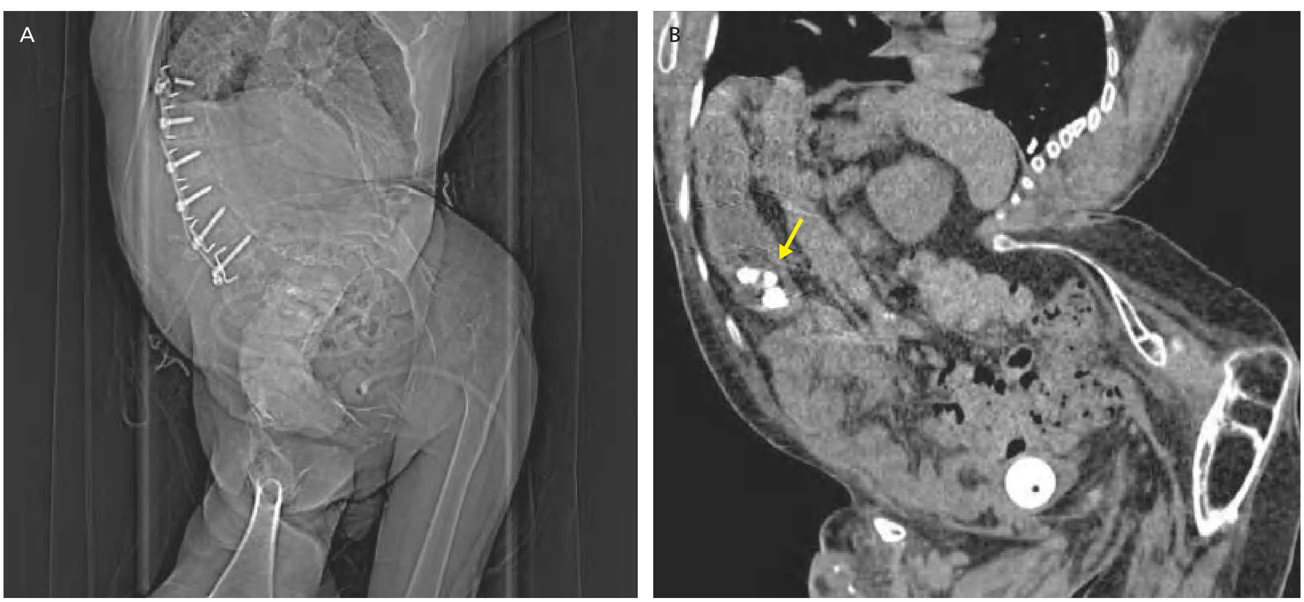

Figure 11.11 (A, B) A patient with severe kyphoscoliosis and a neurogenic bladder. The indication for percutaneous nephrolithotomy was an infected partial staghorn calculus of the right kidney (arrow). Contrast incidentally fills the foley catheter balloon in B. The patient could not tolerate either prone or supine positioning, thus lateral decubitus positioning was used without flexion of the OR table.

patients, the loss of bony landmarks, distorted position of abdominal organs in relation to the target kidney, and difficulties with imaging secondary to X-ray penetration and interference from orthopedic hardware make PCNL difficult. To date, there is limited published data describing PCNL in the patient with severe kyphoscoliosis. Gofrit *et al*. described a single case of severe kyphosis preventing prone positioning. In this case, the lateral decubitus position provided good access to the flank. However, an upper pole nephrostomy had been placed in the radiology suite in advance of the procedure and was used to access the renal pelvic and lower pole calculi [3]. Matlaga *et al*. described a technique for computed tomography (CT)-guided access and included six patients with scoliosis in their dataset [25]. Anecdotally, we have used both prone and lateral positions for this population. No position is universally appropriate and adaptability is of paramount importance. Often, when the fluoroscopic window is limited, access must be secured by the interventional radiologist or trained urologist using ultrasound guidance. Additionally, such patients require additional padding as they can be prone to both pressure ulcers and nerve injuries.

Renal anomalies

Urolithiasis in horseshoe kidneys (HSKs) is common, occurring with a reported incidence of 20–60% [26]. The accompanying rotational anomaly results in calyces that are oriented more posteriorly and a renal pelvis that is more anterior than in "normal" kidneys [27]. The lower pole is also oriented more medially and is fixed in the midline by the isthmus that connects it to the contralateral kidney. As a result, upper pole access is preferred as this provides the least angulation looking down the axis of the kidney, and minimizes torque when manipulating stones located in the renal pelvis and lower pole calyces. When puncture is performed through the lower pole calyces, the tract is significantly longer and at a right angle to the renal axis. Consequently, accessing the upper pole may be difficult or even impossible with a rigid endoscope. Finally, the puncture site through the skin is often located more medially, when accessing the mid or lower calyces, and this can result in injuries to the segmental arteries. Together, all these factors favor PCNL in either the prone or lateral positions [28]. Indeed, supine PCNL in the patient with HSK has not been described and is likely contraindicated in this patient population.

Surgical tables for select positions

There are numerous surgical tables available for both general and endourologic procedures, and as such, a review of each is beyond the scope of this chapter. However, the ideal table will be adaptable to the needs of both the patient and surgeon. For PCNL, an OR table should have a radiolucent, carbon-fiber top with narrow side rails for straps or arm rests. To allow the maximum number of positioning options, the table should also have the ability to flex and raise the legs, and have attachments for leg stirrups for the lithotomy position. It should also be possible to slide the table top towards the head or feet. From a technical perspective, the table should also be offset with a narrow base, allowing wide movement of the C-arm and a large imaging window.

Figure 11.12 Modified Skytron carbon-fiber OR table with stirrups. Note the lack of side rails and large, unobstructed imaging window. This model does not flex. To place the patient in the flexed position, appropriate bolsters and positioning devices are required.

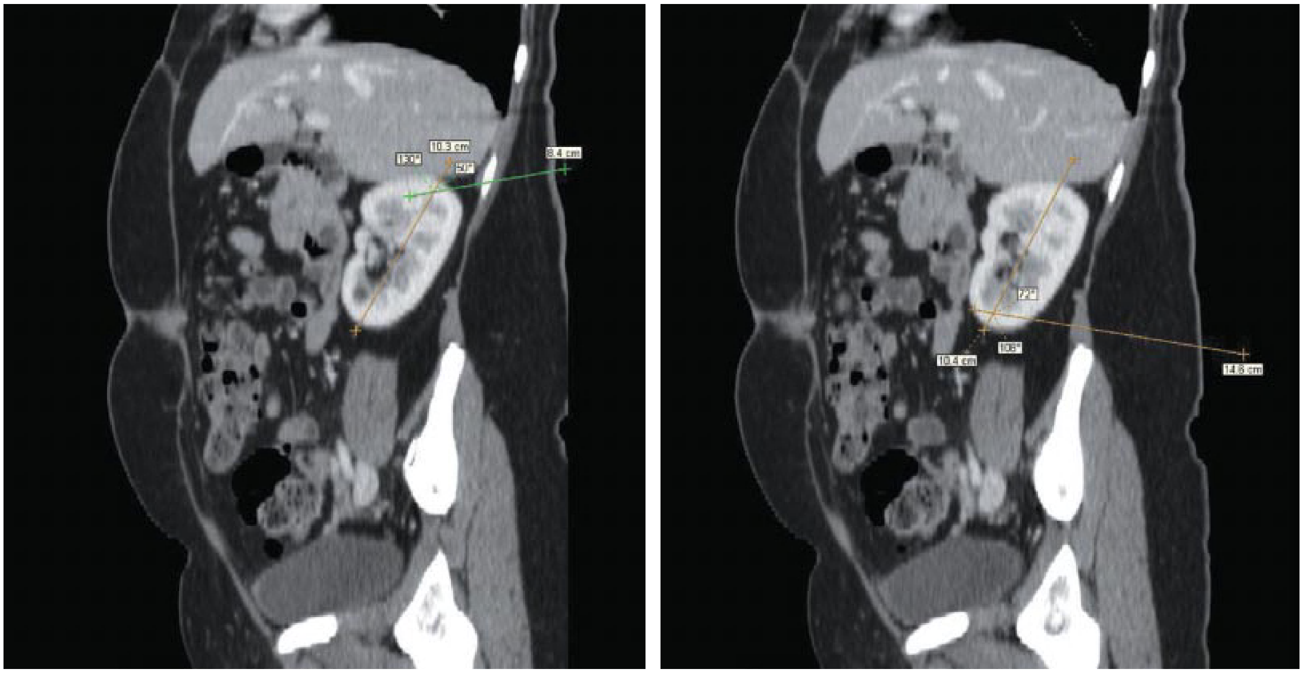

Figure 11.13 Sagittal CT reconstruction of the right kidney demonstrating puncture of upper and lower pole posterior calyces. Upper pole punctures are shorter and more in-line with the uteroposterior junction and renal pelvis, whereas lower pole punctures are longer and have more acute angles, leading to more torque and renal shear.

Finally, it should be possible to accommodate patients up to 600 lb.

The carbon-fiber table developed by Skytron incorporates many of these features (Figure 11.12). This table has recently been modified to confer multiple advantages to the endourologist performing renal access for PCNL [29]. Included among these are a large, unobstructed imaging window that can be used with a C-arm rotated in even the most extreme positions, as well as the ability to position the patient in lithotomy, allowing access to the perineum. One disadvantage of this table is the inability to flex the patient for the prone–flexed position.

Anatomic considerations: renal axis and mobility

Knowledge of renal and retroperitoneal anatomy is essential to performing PCNL with minimal patient morbidity and low risk of iatrogenic organ injury. The kidneys lie in the retroperitoneum with the psoas muscle lying posteromedially, which results in the long axis of the kidneys being deviated so that the upper pole is more medial in the coronal plane. The upper pole is also closer to the posterior abdominal wall and more densely attached to Gerota's fascia [30]. The lower pole is more anterior and freely mobile. These findings can easily be appreciated during open and laparoscopic renal surgery.

There are several implications to these findings. First, puncture of the lower pole may be slightly more difficult as the freely mobile lower pole moves away from the needle and dilators. Second, lower pole tracts tend to be longer and more oblique, making stone removal from upper calyces with rigid instruments more difficult than the converse (Figure 11.13). Percutaneous access into the upper pole is simplified by the more dense attachments of Gerota's fascia, reducing mobility, and the shorter distance from the skin compared to into the lower pole.

Complications of percutaneous nephrolithotomy (see also Chapters 30–32)

Organ injury

Several anatomic studies have attempted to define the relationship of organs to the target kidney and nephrostomy tract. However, the position of the kidneys within the retroperitoneum is dynamic, changing with both respiration and body position. We and others have demonstrated that when the patient is positioned in the

prone or prone–flexed positions, the spleen and liver rotate laterally, away from the kidneys and nephrostomy tract, compared to when the patient is positioned supine [31]. This would make it less likely that either of these organs would be injured with a puncture 30° from the vertical [10]. A study using images from reconstructed magnetic resonance imaging (MRI) scans reaffirmed the preference for more medial puncture to avoid iatrogenic injury to the spleen and liver [32].

Several studies have utilized both CT and MRI to study these changes and estimate the relative risk of iatrogenic organ injury during renal puncture. Organs at risk from upper pole puncture include the liver, spleen, and pleural space [32–34]. In contrast, the colon is most at risk from lower pole access [35]. Risk of organ injury varies considerably amongst published reports. In one study, the predicted risk of injury to the liver or spleen with upper pole puncture was approximately 15%, but decreased to zero by changing body position from supine to prone [33]. In contrast, the same group found that the incidence of retrorenal colon was 4.7% in the prone position and 1.9% in the supine position [36]. In a study of axial and multiplanar reformatted CT scans, Tuttle *et al*. demonstrated that axial CT scans may dramatically overestimate the risk of injury. The risk of organ injury associated with lower pole puncture on axial CT was 6.0% in the supine position versus 15.1% with the patient prone; however, for oblique parasagittal CT reconstructions, the risk was decreased to 3.0% and 0%, respectively [35]. These findings are more in keeping with clinical series demonstrating low rates of organ injury. The lack of a standardized approach may also account for the variability in these reports. In the largest clinical series, the rate of bowel injury was 0.06% of almost 1600 procedures, with no cases of splenic or liver injury [17]. Others have reported similarly low rates of organ injury [11, 12, 37]; however, in some series, access was obtained in the radiology suite.

Valdivia Uria *et al*. and Falahatkar *et al*. state that the colon "floats away from the kidney when the patient is in the supine position" [9, 16]. Our CT studies did demonstrate that the colon was more medially situated and theoretically more prone to injury in the prone and prone–flexed positions compared with the supine position; however, the overall effect was minimal. Anatomically the colon is attached laterally to the peritoneum of the side wall of the abdominal cavity at the level of the kidneys and movement is restricted. The more lateral approach of the supine position would therefore still be more likely to result in the rare complication of colonic injury, which has been reported in this position [38].

Thoracic complications

The risk of pleural injury is of considerably greater concern. The diaphragm inserts onto the 12th and 11th ribs with the pleural reflection running horizontally and crossing the midpoint of the 12th rib in the majority of patients. The risk of pleural injury is therefore related to the position of the kidney in the retroperitoneum, the pleural reflection, and the calyx chosen for access. The majority of pleural complications occur with upper pole access. Significant complications include pneumothorax, hydrothorax/hemothorax, and empyema. In a study by Munver *et al*., the incidence of thoracic complications was 23.1% above the 11th rib, but dropped to just 1.4% above the 12th rib. The overall complication rates ranged from 4.5% for subcostal access to 9.7% above the 12th rib, and 34.6% above the 11th rib [39]. We have previously demonstrated that prone–flexed positioning results in inferior displacement of the kidneys within the retroperitoneum, an effect which could result in fewer thoracic complications [10]. In an update of our previous report including data from the last 318 patients in our unit to be treated in the prone–flexed position, 16 (5.4%) of the tracts were above the 11th rib, 120 (40.8%) were above the 12th rib, and 158 (53.7%) were infracostal. There were only four pleural complications requiring chest drain insertion, representing 2.6% of the supracostal cohort [40].

Hemorrhage

To prevent bleeding, the most important aspect is the end-on puncture of a posterior calyx. Using 3D polyester resin endocasts, Sampaio *et al*. demonstrated that the risk of arterial injury was highest from infundibular puncture and that the calyceal fornix provided the safest route of access [41]. Normally, the upper pole of the kidney is more medially and posteriorly located than the lower pole. Consequently, an upper pole posterior calyceal puncture lateral to the paraspinal muscles will result in access being more in line with the axis of the kidney. This will result in less torquing of the kidney to reach the lower calyces and less chance of the parenchyma splitting and bleeding (Figure 11.13). An angled tract that is not in line with the infundibulum or renal axis, or a puncture of the lateral calyces will require more torque to reach the stone, which may result in unnecessary bleeding and increased transfusion rates. Choice of the appropriate percutaneous tract through a posterior calyx in line with the infundibulum will allow the operator to achieve a transfusion rate for PCNL of approximately 1% [17]. In

an update of our previous report reviewing data from our most recent 318 consecutive patients, no patient required blood transfusion or angioembolization [40].

Complications specific to patient positioning

Anesthetic considerations (see also Chapter 8)

Anesthetic concerns garner much attention in prone percutaneous surgery and have been the driver of much of the renewed interest in supine PCNL. The greatest risk of airway loss is when the patient is positioned prone. For this reason, secured endotracheal anesthesia is preferred [42]. However, even with a cuffed endotracheal tube, problems may occur. Obstruction of the tube may occur due to kinking or secretions draining under gravity in this position [43]. Fortunately, such concerns remain largely theoretical and complications are limited to case reports.

Another concern has been the maintenance of prone anesthesia in obese patients or those with cardiovascular or respiratory compromise. Although we have found that the prone–flexed modification may further increase airway pressures in obese patients, necessitating a reduction in patient flexion, we have not found it necessary to revert to conventional prone positioning. As with other authors, in the morbidly obese patient, we favor lateral or lateral–flexed positioning as this avoids abdominal compression and allows the anesthesiologist free access to the patient's airway [2, 3]. Others have reported using the lateral decubitus position in high-risk patients under regional anesthesia [44], as well as awake endotracheal intubation with prone self-positioning [23] as ways to overcome these difficulties.

Cardiovascular changes

The greatest body of research related to the effects of prone and prone–flexed patient positioning comes from spinal surgeries, where the impact of patient position on both physiology and surgical outcome has long been recognized. Hemodynamic changes related to patient positioning remain controversial and likely depend on the underlying cardiovascular status of the patient, the precise body position, and the use of saddles/bolsters. It is generally agreed that prone positioning causes a decrease in cardiac index (CI). However, this is not felt to be clinically significant. In a study of 19 patients, Hatada *et al*. concluded that the drop in CI presented no significant challenge to the maintenance of anesthesia [45]. Other groups have also reported this finding [46, 47]. In the prone and prone–flexed positions, mean arterial pressure (MAP) appears to be maintained due to an increase in systemic vascular resistance [47].

Prone positioning may also lead to transient IVC obstruction. In spinal surgery, this has led to speculation that impeded venous drainage may contribute to increased bleeding during surgery [48]. Whether this may also play a role in blood loss during renal surgery remains unknown. It has been shown that relieving abdominal compression by placing a bolster under the patient's chest and padding of the anterior superior iliac crests can dramatically decrease the effect [49].

In rare circumstances, cardiac resuscitation may be necessary in the prone patient. When possible, it is advisable to return the patient to the supine position and to have a stretcher standing outside the OR for this purpose. This allows access to the precordium for both chest compressions and defibrillation. However, when there is need for prolonged delay in repositioning due to instrumentation protruding from the flank, successful resuscitative efforts with the patient positioned prone have been reported [50, 51].

Respiratory changes

As with cardiovascular changes, changes in pulmonary physiology vary considerably with patient position, body habitus, and the amount and type of padding/support used. Although tidal volumes and inspiratory flow rates are preserved in the ventilated patient, functional residual capacity (FRC) consistently increases with a change from supine to prone position [42]. One study found that prone positioning did not significantly affect compliance and that respiratory resistance increased only slightly in nonobese patients. As both FRC and PaO_2 markedly increased from the supine to the prone position, the authors concluded that during general anesthesia, prone positioning did not have a negative effect on respiratory mechanics, instead improving both lung volumes and oxygenation [52]. Interestingly, these improvements were maintained in a similar study in anesthetized and paralyzed obese patients in the prone position [53]. It has been hypothesized that improvements in gas exchange may be due to changes in pulmonary blood flow and redistribution of lung ventilation, resulting in better V/Q matching [42]. Importantly, the requirement for free abdominal and chest-wall movement cannot be overemphasized in the surgical patient.

Ophthalmic complications

Eye injuries resulting from surgery are extremely rare, with an incidence of approximately 0.1% following nonocular surgery [54]. Corneal abrasions account for the majority of these injuries, but rarely result in vision loss. In the prone position, there is also a theoretical risk of blindness, due to increased intraocular pressure resulting in ischemic optic neuropathy (ION). Fortunately, this complication is rare and has mainly been reported during spinal surgery, especially with prolonged OR times in excess of 6 h in the prone position [55, 56]. We are unaware of any cases following PCNL.

Nerve injury

Positioning-related peripheral nerve injuries occur secondary to stretch, ischemia, or compression. The combined factors of time, mechanical pressure, and immobility place patients at risk for these complications. Recovery can be variable and is directly related to the severity of the injury.

Special care must be taken with patients in the prone position as they are susceptible to brachial plexus injuries [57]. Such injuries are most commonly due to nerve stretch from extreme shoulder abduction; however, external compression can also play an important role. Prolonged surgical procedure has also been suggested as a contributing factor. Typically, these injuries present as painless motor dysfunction. To prevent this complication, some authors recommend tucking the arms at the patient's side during the procedure. We find that abduction of the shoulder to approximately 90° with elbow flexion relieves undue stress. Ideally, the arm should be well padded and rest below the level of the patient's chest. Additionally, for patients in the prone and prone–flexed positions, the head must be maintained in a neutral position to prevent lateral flexion. Fortunately, the prognosis for these injuries is usually good. In one study, following a cohort of 22 patients with brachial plexus injury, including 14 following noncardiac surgery, complete recovery was achieved in 79% [58].

Nerve compression injuries may also occur in other operative positions. In the lateral position, the ulnar nerve is at risk from the edge of the OR table. The majority of these injuries can thus be prevented by adequate padding at the elbow and supination of the dependent arm [59]. In particular, flexion of the elbow of greater than 90° is a known risk factor and is due to shrinkage of the cubital tunnel, resulting in compression of the nerve [60].

Injury to the peroneal nerve has commonly been described in association with the dorsal lithotomy position. Many surgeons use Bierhoff leg holders when placing patients in this position. Long duration of the procedure has been implicated in this type of injury [61]. General guidelines for use of these supports include: (1) slow and simultaneous placement of the legs into their final position, and (2) limiting the amount of hip flexion, abduction, and lateral rotation [57]. In the lateral decubitus position, compression of the unpadded fibular head against the OR table during nephrectomy resulted in peroneal nerve injury in one patient [62].

Sciatic nerve compression between the OR table and the ischial tuberosity has also been known to occur in patients in the semi-lateral position as well as in the lithotomy position [57, 61].

Fortunately, the great majority of intraoperative nerve injuries are preventable. A high level of suspicion is important when recognizing these injuries as patient complaints in the early postoperative period may be easily dismissed. With careful attention to patient positioning, the use of adequate padding, and awareness of patient comorbidities such as skeletal deformity are all essential components. When nerve injuries do occur, prompt referral to a neurologist who specializes in these types of injury is required.

Prone versus supine percutaneous nephrolithotomy

In an attempt to overcome some of the difficulties associated with prone positioning, there has been a resurgence of interest in PCNL performed with the patient supine (Table 11.3). The first report on supine PCNL, by Valdivia Uria *et al*. in 1998, included 557 patients [9]. In this position, puncture is performed under fluoroscopic or ultrasound guidance either in or anterior to the posterior axillary line (see Chapter 10). This distinction is important as the resulting tract is significantly more lateral than the access used in prone or lateral PCNL. In their original report, Valdivia Uria *et al*. expressed a preference for puncture of anterior calyces, with low complication rates; however, transfusion rates were not reported. Other authors have similarly found that puncture of anterior calyces is often necessary in the supine position [15, 63]. As noted above, rates of adjacent organ injury are rare when performing PCNL. In his original report, Valdivia Uria stated that the colon "floats away from the kidney when the patient is in the supine position" [9]. Our data from axial, triphasic CT scans performed with the patient prone, prone–flexed, and supine supported this statement. However, the overall effect was small and would likely be mitigated by the more laterally placed tracts necessary with supine PCNL. Of 1720 supine procedures reported in the literature to

Table 11.3 Summary of the supine/Galdakao-modified supine Valdivia (GMSV) patient position.

Technique	Advantages	Disadvantages
Originally performed with the patient supine and the ipsilateral leg fully extended A 3-L saline bag is placed under the ipsilateral flank GMSV includes modified lithotomy position with extension of the ipsilateral leg and abduction of the contralateral leg	May perform ureteroscopy and nephroscopy simultaneously Patient repositioning is unnecessary Improved surgeon comfort Theoretically reduced radiation exposure Stones may spontaneously evacuate at calyx of entry due to dependent drainage Fewer cardiovascular and respiratory effects May be performed without endotracheal intubation	Instrument movement is limited by the OR table and the patient's hip Pelvicalyceal system is collapsed and may contain air, impairing visibility Upper pole puncture is more difficult or impossible Many calyces are dependent and collect fragments Placement of multiple tracts is difficult, limiting use in staghorn calculi Results in longer nephrostomy tracts, sometimes requiring longer instruments Longer OR times when treating staghorn stones Ventilation may be impaired in morbidly obese patients May be associated with higher transfusion rates

date, only one case of bowel injury has been reported (0.00058%) [38].

Bleeding following PCNL is another area that deserves attention. A review of all studies published to date demonstrated an overall transfusion rate of 4.6% (range 0–20%) with PCNL performed in the supine position [15, 16, 38, 63–72]. The higher transfusion rates may be partly due to renal shear, as puncture of an anterior or lateral calyx in the lower pole would result in more manipulation when using a rigid endoscope to access the full length of the collecting system. Additionally, end-on fluoroscopic views of the calyces in this position are obstructed by the patient's spine and side-rails of the OR table, particularly in oblique views. As a result, the triangulation method of fluoroscopic puncture may be necessary or, more commonly, ultrasound-guided access. In the latter case, special expertise may be necessary to perform end-on calyceal puncture to avoid the intrarenal arterial injuries that can be the cause of profuse bleeding during PCNL [41]. Four studies have performed a direct comparison of prone and supine positioning during PCNL by the same surgeon [15, 16, 38, 63]. Due to small sample sizes, no significant difference in transfusion rate was noted by any group. However, when considered together, the transfusion rate for PCNL performed in the supine position was 8.8% versus 4.3% when performed prone (182 and 207 patients, respectively; $P = .07$).

An argument given by proponents of the supine technique has been that it is more ergonomic, and facilitates stone clearance through spontaneous evacuation from the dependent nephrostomy tract. However, in this position, stone fragments also collect in the dependent posterior calyces rather than the renal pelvis, as is the case when the patient is prone. Dependent nephrostomy drainage in this position also results in a collapsed system, often containing air bubbles that may interfere with visualization. Finally, the supine position can also result in restricted mobility of the nephroscope due to conflicts with the OR table.

In a review, de la Rosette *et al*. examined the effect of patient positioning, concluding that for obese patients or those with staghorn calculi, the prone position was associated with similar bleeding rates, but decreased operative times, and slightly improved stone-free rates compared to the supine position [73].

Conclusions

Appreciation of the calyceal anatomy and the ability to choose the appropriate posterior calyx for percutaneous access in the prone position will allow the operator to perform the procedure with minimal morbidity. Prone–flexed positioning is a simple modification that is well tolerated by the patient and offers significant surgical advantages. The lateral position is well-suited to the morbidly obese patient, while the lateral-flexed position adds further advantages and is familiar to all urologists.

CHAPTER 13

Percutaneous Renal Access Under Fluoroscopic Control

Norberto O. Bernardo

Hospital de Clínicas José de San Martín, University of Buenos Aires, Buenos Aires, Argentina

The last years of the 1970s and the early 1980s will probably be remembered by urologists as a time of tremendous changes, in particular the whole concept of minimally invasive surgery and the development of percutaneous surgery, which have shown spectacular clinical results and reduced the morbidity of open surgery [1]. Percutaneous stone extraction was first described more than 30 years ago and has become an increasingly common intervention for patients with stone disease [2, 3], evolving into a safe and effective treatment for patients with large or otherwise complex stone disease. However, despite the increasing use of percutaneous renal surgery, Lee *et al*. reported that only a minority of urologists, 27% of who have trained in percutaneous access, actually gain their own access for percutaneous nephrolithotomy (PCNL) [4]. One of the more common reasons given by respondents for not doing so was inadequate skills in the techniques of access.

The placement of percutaneous access into the intrarenal collecting system is one of the most critical aspects of percutaneous renal surgery. Image guidance is a critical factor for the performance of percutaneous minimally invasive procedures, which are being used with ever increasing frequency. Procedures such as PCNL are not performed without image guidance. The puncture of the kidney, insertion of guidewires, establishment of the percutaneous tract, and the disintegration and removal of stones are based on appropriate image guidance. For percutaneous renal surgery using fluoroscopy, access must be gained: different forms of access have been developed, all with the indispensable assistance of the image intensifier [5].

The first percutaneous nephrostomy to decompress an obstructed kidney was described by William Goodwin in 1955 [6]. However, removal of a renal calculus via a percutaneous tract established specifically for that purpose was not performed until 1976, when Fernstrom and Johansson used the technique successfully in three patients [7]. In their series, the tract was slowly dilated under fluoroscopic control over a 7-day period to a size sufficient for stone extraction. Similarly, Alken *et al*. in their experience with PCNL established access to the renal collecting system over the course of weeks, by repeatedly dilating it with hand-shaped polyethylene tubes of increasing size [8]. He subsequently developed the metal telescope dilators to solve the problems met during the treatment of his first 21 patients, which accelerates the procedure and allows percutaneous stone removal to be performed in a single session with a delicate set of instruments. In 1982, Smith *et al*. described the rapid dilation of the nephrostomy tract in minutes with no untoward effects, which revolutionized the field of percutaneous stone surgery and contributed to the demise of open surgery [9]. Since that time the percutaneous approach has generated wide interest among the pioneers of endourology, and they developed and popularized most of the basic principles in this area in the late 1970s.

Fluoroscopy

Imaging equipment in percutaneous renal surgery typically uses radiation for image formation and guidance during access and tract dilation.

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Fluoroscopy is useful during the advancement of guidewires, tract dilation, stone removal, and nephrostomy placement, providing realtime depiction of the collecting system and the stones therein. Percutaneous renal surgery is performed with a combination of fluoroscopic and endoscopic visualization of the collecting system. Fluoroscopy is a two-dimensional (2D) method and provides limited information regarding the surrounding soft tissue. Nevertheless, it has proven to be an invaluable tool for the performance of percutaneous procedures of the kidney and collecting system.

Radiation exposure

All parameters of fluoroscopy affecting image quality, reproducibility, and radiation output from each radiographic unit must be evaluated routinely to ensure optimal image quality while minimizing the radiation dose [10]. The endourologist can improve their imaging techniques and minimize both their and the patient's radiation exposure with no concurrent loss of image quality.

When attempting to obtain a diagnostic-quality image and the image is underpenetrated, and given the choice between increasing the total number of X-rays (mA) or the penetrability of the X-rays already present (kVp) to improve the image, the kVp should be increased initially as this will not increase the radiation output [11]. Collimating the image to the minimum size necessary for performing the work will reduce the amount of unnecessary radiation to which the patient and anyone else in the room is exposed.

The radiation output from the X-ray tube should have been evaluated within the past year by a radiologic physicist, who determines whether the unit's radiation output is within legal limits as well as optimal for each examination.

Radiation entering the patient is absorbed, scattered, or transmitted as a function of the density of the tissue it encounters. The contribution from tube leakage, and scatter from machine components and from the patient comprises the secondary radiation field and this is of the most concern to persons in the room during fluoroscopic imaging.

Radiation "spreads out" in a three-dimensional space with a discrete or fixed number of photons spreading out into successively larger spaces. As a result, the area geometrically increases as a function of distance from the source. Increasing the distance from the source is one of the least expensive and most dramatic ways to reduce the dose of radiation to which operating personnel are exposed. By doubling the distance from the source, the radiation is reduced to one-fourth of its original intensity because the same number of photons is in a space that is four times larger. Similarly, by tripling the distance, radiation is reduced to one-ninth. Moving 3 feet further away from an initial distance will reduce the dose by 89%.

Shielding, whether provided by lead aprons or thyroid shields, is a method of last resort. They provide excellent protection and should always be worn by those who work near the fluoroscopy table to limit the dose of radiation to which they are exposed. When fluoroscopy is performed, the radiation dosimeter badge is worn on the collar, outside the apron. As a result of this technique, the actual effective whole-body exposure is up to 99% lower than the dose measured by the badge [12].

Component positioning on the C-arm can significantly influence scattered radiation fields. When the image intensifier is placed above the patient, and the tube is shielded by the table, both leakage and scatter radiation are minimized.

The introduction of digital radiography has contributed to the reduction of radiation exposure as well as to the improvement of image quality [13]. The combination of digital radiography with image storage systems and use of image processing systems resulted in the prevention of unnecessary image duplication and facilitated preoperative planning. A new generation of equipment has been designed with patient and operator dose reductions central to its development. Pulsed fluoroscopy and digital imaging have become available that reduce the dose of radiation delivered to the patient. Digital equipment eliminates the need for film; the information is electronically captured and manipulated by computer. As a result, the image can be enhanced, providing a sophisticated tool for dynamically evaluating patient organ function using videotape techniques.

Radiation exposure can be a deleterious problem in percutaneous surgery, especially for the surgeon [14, 15]. The use of ultrasonography can eliminate the side effects of radiation exposure during fluoroscopy-guided PCNL, and it can be used as a reliable method for localization of renal stones, especially nonopaque stones that are not visible with fluoroscopy. Also B-scan sonography can be used as a tool for localization of intrarenal arteries and avoidance of puncture by a Chiba needle.

Ultrasound versus fluoroscopy-guided access (see also Chapter 12)

The advantages of ultrasound- over fluoroscopy-guided access into the collecting system include reduction of exposure to radiation for the urologist and operating room personnel. In pregnancy and in patients with transplanted, horseshoe, or ectopic kidneys, ultrasound represents the modality of choice [16, 17]. Another advantage is proper localization of the adjacent organs for prevention of injury. The main disadvantage of this

modality is the difficulty and the need for greater care when the collecting system is only mildly dilated.

Ultrasound has been used by several groups for the guidance of PCNL, especially during the puncture of the collecting system [18].The performance of puncture with ultrasound guidance and without use of fluoroscopy has also been reported [19]. While ultrasound can be a useful complement to access the kidney, it should be emphasized that fluoroscopy is an indispensable component of safe percutaneous surgery.

Preoperative images

Conventional computed tomography (CT) has been used for diagnosis of urologic diseases for many years. Recently, unenhanced helical CT has become a serious alternative to intravenous urography [20]. For preoperative planning, helical CT depicts the extent, orientation, and location of renal calculi, which are useful for access selection in percutaneous procedures. In addition, the anatomic relationships of the collecting system with surrounding organs are delineated, and the performance of a safe puncture is possible [21]. Nevertheless, the inability to provide realtime imaging capability has prevented wider application of CT in interventional procedures [22].

The three-dimensional (3D) reconstruction of CT images for planning of percutaneous procedures has been reported to be feasible and accurate. With the use of 3D rendering software, the anatomic relationships of the collecting system are provided, and access selection is facilitated. The usefulness of 3D-reconstructed CT images, however, is not widely accepted [23]. 3D CT-rendered images that combine axial CT, CT urography, and angiography have been used for preoperative planning of urologic procedures, such as nephron-sparing surgery. Renal lesions and vessels can be accurately detected [24, 25]. Recent improvements in CT technology provide rapid and continuous reconstruction of CT raw data and provide realtime CT imaging (CT fluoroscopy) [26, 27].

Magnetic resonance imaging (MRI) provides better depiction of the soft tissue in comparison with fluoroscopy and CT, but remains unreliable for the identification of stones in the collecting system or ureter. MRI can be obtained without exposure to ionizing radiation. Thus, the technique may be considered as an alternative to ultrasound in selected cases such as the pregnant patient. Nevertheless, the strong magnetic field used interferes with ferromagnetic foreign bodies or electronic medical devices that are frequently carried by patients, although improvements in electronic medical devices have minimized this problem [28]. Newly introduced multisensor detector and faster image processing systems, as well as more advanced MRI scanners, have rendered realtime imaging a reality (MR fluoroscopy). The latter technique has been used in interventional cardiology [29]. Percutaneous nephrostomy placement has been performed with the use of open configuration MRI. MR urography represents an evolving imaging modality that allows optimal noninvasive evaluation of many abnormalities of the urinary tract. The application of several technical modifications provides adequate information for preoperative planning and postoperative assessment [30].

Each of these new technologies offers several potential advantages over the traditional percutaneous approach under fluoroscopic control. It should, however, be stated that all of these technologies are in a nascent stage of development. For that reason it is necessary to reinforce the basic concepts governing the realization of a conventional procedural approach to the kidney under fluoroscopic control. While this conventional approach is appealing, only a small percentage of urologists are familiar with it [4], and various training models are essential for consolidating the use of this surgery [31, 32].

Percutaneous renal access under fluoroscopic control

In general, all patients undergoing any percutaneous renal procedure are given a general anesthetic. Then the patient is placed in a lithotomy position for cystoscopy, with insertion of a 6F open-end ureteral catheter under fluoroscopy guidance.

A retrograde urogram then delineates the ureteral anatomy, as well as the exact stone location, degree of hydronephrosis, and the image of the selected calyx in order to plan the approach to the collecting system if this is deemed necessary [33].

The rigid cystoscope is used to place a 0.038-inch Teflon-coated guidewire into the upper collecting system. When a tortuous area blocks the progress of the guidewire, a wire with a hydrophilic coating must be used. This wire is composed of an alloy core, a polyurethane jacket, and a thin hydrophilic polymer as the outermost layer. When in contact with fluid, the polymer binds water to create a lubricious coating with greatly diminished friction, avoiding excessive edema and creation of a false passage. When the guidewire is in position, the 6F catheter is advanced over it to the renal pelvis, and the endoscope is removed.

A 16F Foley catheter is inserted and attached to a drainage bag at the same time. Both catheters are tied with 2-0 silk to secure them in place. It is helpful to connect an empty syringe to the Luer lock adapter at the end of the ureteral catheter to prevent urine leakage.

The patient is positioned prone to allow posterior access. The patient is moved slowly and gently to allow

the body to adjust to the position change. A foam rubber pillow is placed under the head to prevent it from being angulated excessively in relation to the trunk. The endotracheal tube is placed in the side slot of the foam pillow, making sure that the tube is unobstructed and free from kinks. To reduce resistance to breathing, the chest and abdomen are elevated on two foam rubber rolls that extend from the shoulder to the hip. Knee donuts padded with sheepskin inside the ring are positioned between the knees and the operating table to protect the bony prominences. A foam rubber roll is placed anterior to the ankles. The arms are flexed and secured on padded arm boards, and the elbows are protected with sheepskin pads. At this time, the 2-0 silk tie securing the two catheters together is cut and discarded. The intravenous extension tubing is connected to a 60-mL syringe containing 25% diatrizoate (Hypaque) solution, and the tubing is primed. The nurse removes the empty syringe from the ureteral catheter and attaches the syringe and tubing to the Luer lock adapter of the ureteral catheter.

Recently, several reports have been published of percutaneous renal surgery in the supine position [34, 35]. This has potential advantages over the prone position for PCNL but it has not been adopted by most urologists (see Chapter 10). The modified supine position preserves cardiovascular and ventilatory dynamics and allows better access to the respiratory tract. Additionally, the bowel slips away from the puncture area, lowering the risk of it being damaged. PCNL with the patient in a modified supine position may be considered for most patients, especially if concomitant ureteroscopy is planned [36].

The percutaneous nephrostomy is created via an upper, middle, or lower calyx. Thorough evaluation of the renal collecting system anatomy is essential prior to definitive percutaneous puncture for access tract creation. The information provided by preoperative helical CT is very valuable at the time of puncture under fluoroscopic control [37], as it identifies the most suitable place to set the path of the needle from the skin to inside the calyx that has been chosen for tapping. A CT scan can assess the presence of adjacent organs brought into the path of the needle. In this case, there is the option to change that path at the time of puncture under fluoroscopic control or to decide that percutaneous access is contraindicated.

When deciding where to make the puncture, areas of parenchyma should be considered that are thick enough to maintain a stable needle path and prevent subsequent development of a fistula. Also, it is desirable to identify those calyces for which surrounding thickness of parenchyma will promote their spontaneous closure of the puncture. Areas of kidney with an extremely thin parenchyma should be avoided.

Also, the information provided by helical CT will allow paths to be planned that avoid simple cysts, which sometimes are present in the renal parenchyma and are frequently not picked up on fluoroscopy.

The collecting system is opacified with direct injection through the ureteral catheter of contrast. A posterolateral transparenchymal puncture minimizes the chance of injury to the major renal vessels. The chosen posterior calyx is visualized with the C-arm fluoroscopy unit in the posteroanterior direction initially. The posterior calyces are positioned 20° posteriorly to the frontal plane of the kidney in most right kidneys, and 70° posterior to the frontal plane of the kidney in most left kidneys. In a normally rotated kidney, the frontal plane of the kidney is 30° posterior to the coronal plane of the body.

Percutaneous access to the upper urinary tract through a calyx must meet five conditions that guarantee safe access and avoid complications: access is performed from a posterolateral position, through the renal parenchyma, toward the center of the calyx posterolaterally, and toward the center of the renal pelvis, and as a result of these four conditions, the trajectory does not damage any major blood vessels.

There are two primary methods used to gain fluoroscopy-guided percutaneous renal access: the ''bullseye'' technique and triangulation [38, 39]. Both techniques need a target, most commonly generated by opacification of the collecting system with iodinated contrast that is administered retrograde via a ureteral catheter. A calyceal entry point is selected to avoid the larger vascular structures that are found at the level of the infundibulum.

As with most percutaneous access techniques, the bullseye technique requires fluoroscopy to monitor and guide the procedure. To this end a ureteral catheter is placed and the patient is positioned as described above. With the C-arm in the 30° position, an 18G diamond tip access needle is positioned, so that the targeted calyx, needle tip, and needle hub are in line with the image intensifier, giving a bullseye effect on the monitor. In effect the surgeon is looking down the needle into the targeted calyx. The needle is advanced in 1–2-cm increments using a hemostat to minimize radiation exposure to the surgeon. Continuous fluoroscopic monitoring is performed to ensure that the needle maintains its proper trajectory. Needle depth is ascertained by rotating the C-arm to a vertical orientation. If the needle is aligned with the calyx in this view, the urologist should be able to aspirate urine from the collecting system, confirming proper positioning.

The triangulation technique is based on simple geometric principles and is guided by biplanar fluoroscopy; one plane is anteroposterior to the line of puncture and the other is oblique. The anteroposterior view may be

considered to be in a plane parallel to the axis of puncture and is used to monitor mediolateral (left–right) adjustments. The oblique view gives information regarding depth to the site of puncture and is used to monitor needle adjustments in the cephalad–caudad (up–down) orientation.

The tip of the needle is oriented towards the calyx to be punctured in both the anteroposterior and oblique planes. Left–right adjustments are limited to the anteroposterior view only, and cephalad–caudad adjustments are limited to the oblique view. When making adjustments in the mediolateral axis, care should be taken not to inadvertently move the needle in the cephalad–caudad axis, and vice versa. In most cases, it is helpful for the surgeon to rest their arm on the patient during the access part of the procedure, as this minimizes unintended drifting of the needle away from the targeted axis and also provides additional needle stabilization.

To decrease the radiation exposure to the surgeon's hands, the C-arm should be oriented with the image intensifier angled toward the head of the patient. Whenever possible, the iris of the fluoroscope should be kept as small as possible, to further minimize stray radiation exposure. Once the needle is aligned with the targeted calyx in both the mediolateral and cephalad–caudad orientations, it is advanced with continuous fluoroscopy. The needle should always be advanced in the oblique view, which will allow for the assessment of the depth of the needle's penetration. It is helpful for the anesthesiologist to hold the patient's respirations while the needle is being advanced, to avoid having to "hit a moving target", as well as to minimize the risk of an inadvertent transthoracic puncture. After advancing the needle several centimeters in the oblique view, the anteroposterior view should be examined to confirm that the mediolateral trajectory of the needle is still properly aligned to the target. If necessary, the needle trajectory can be readjusted to maintain proper targeting. Again, it is critical not to alter the access needle's orientation in one plane while making adjustments in the other plane, particularly when advancing the needle.

Several groups have reported refinements in techniques, incorporating elements of the bullseye and triangulation methods, proposing new approaches, describing adjuncts, and using new technology. Mues *et al*. described a geometric model to create a plane of coincidence between the C-arm and the needle, each at the same angle of 20–30° from the targeted calyx, but in opposite directions [40]. For lower pole access, the C-arm is rotated cranially 30° from the vertical plane, and a needle is advanced from a position distal to the calyx, rotated caudally 30° from the vertical plane. For mid-renal and upper pole calyceal access, the C-arm is rotated 20° away from the surgeon, and a needle is advanced from a position lateral to the calyx, at an angle of 20° toward the surgeon from the vertical plane. In either case, the C-arm remains fixed, and the needle is advanced until the point of coincidence between the calyx and the needle tip is reached. This technique purportedly eliminates the need for C-arm rotation, thus potentially reducing C-arm manipulation and fluoroscopic exposure time. This technique, however, requires a plumb, protractor, and ruler to calculate and confirm the necessary measurements.

Another recently proposed modification by Sharma and Sharma represents a hybrid of the bullseye and triangulation techniques [41]. The posterior calyx that provides the best access for stone clearance is selected. The initial puncture needle is held at this point. The needle with its overlying hub in the same line as the calyx creates a bullseye effect on the C-arm monitor. The site on the skin corresponding to the target calyx is thus determined, and its position is marked with a hemostat as point A (see Video 13.1). We place an intramuscular needle at this point instead of a hemostat. Then, under direct vision, the needle is placed vertically and the puncture is made at this point in the subcutaneous cellular tissue at a depth of about 1 cm (Figure 13.1A). The visual control of the needle in the vertical position reduces fluoroscopic exposure to a few seconds. Subsequently, a brief fluoroscopic exposure is used to check the position of the needle and it is shown on the screen as a point. The trajectory of the line of puncture of the needle into the dorsal area represents an imaginary line through the selected calyx in the anteroposterior direction. However, this trajectory does not meet all five requirements for optimum puncture, described above, as the needle is not directed toward the center of the renal pelvis.

The C-arm is then angled toward the surgeon, 30° from the vertical in the axial plane. With the ventilation suspended in end expiration, the second puncture needle is held over the targeted calyx in such a way that the needle with its hub is in the same line with the calyx, which leads to a bullseye effect on the C-arm. This particular point on the skin is punctured with an intramuscular needle and is taken as point B (Figure 13.1B) (see Video 13.2). This position represents an imaginary line that is projected onto the center of the selected calyx. Again, all five requirements for safe renal puncture are not met because the trajectory is not toward the center of the renal pelvis. This position is checked in relation to the 12th rib. Visually observing the trajectory of the two small needles placed in the lumbar area, the intersection of two lines coincides with the desired calyx.

The distance between the two needles is measured. (Figure 13.2A). The C-arm is then brought back to its vertical position. Now the line of puncture is determined in alignment with the infundibulum from point A. Along this point line, the point B1 is marked. The

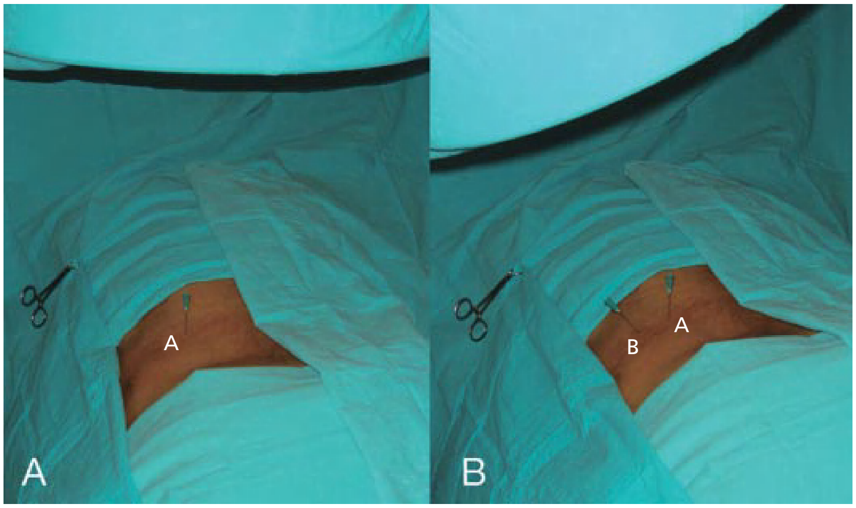

Figure 13.1 (A) The intramuscular needle with its overlying hub in the same line as the calyx creates a bullseye effect on the C-arm monitor. The needle is placed upright and puncture is done at this point at a depth of about 1 cm in the subcutaneous cellular tissue. (B) The C-arm is angled 30° toward the surgeon. The second needle is held over the targeted calyx in such a way that the needle with its hub is in the same line with the calyx, which leads to a bullseye effect on the C-arm.

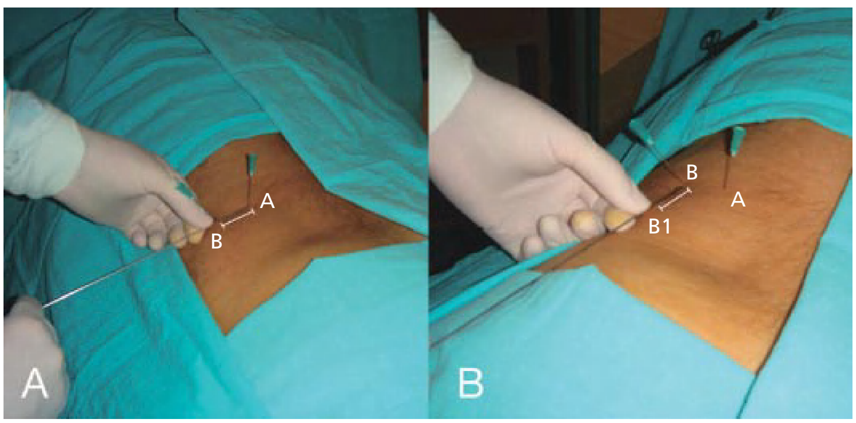

Figure 13.2 (A) Distance between the two needles is measured. (points A and B). (B) B1 is the point where the skin will be punctured for renal access. The distance between points A and B1 is equal to or greater than the distance between the intramuscular needles.

distance between points A and B1 is equal to or greater than the distance between the intramuscular needles (points A and B) (Figure 13.2B). The point B1 is the point where the skin is punctured for renal access. A small incision is then made at point B1 and the 18G needle is introduced for 1–1.5 cm (Figure 13.3). Now, with the C-arm in the 90° vertical position (i.e. parallel to the line of puncture), the mediolateral (right to left) adjustments are made. Then the C-arm is tilted toward the head of the patient by 30° and adjustments are made in the cephalad and caudal orientation of the line of puncture. The needle orientation is maintained in one plane while making adjustments in the other plane. With the C-arm in the oblique orientation, the needle is advanced with ventilation suspended in full expiration. Under fluoroscopic control and from this position, the 18G needle is advanced towards the point of intersection of the two lines that project both intramuscular needles to reach the selected calyx (see Video 10.3). This is the ideal path and the only one that meets the five requirements described above of a safe percutaneous renal puncture.

When the tip of the needle appears fluoroscopically to be within the collecting system, the needle trocar is removed, leaving only the needle cannula in place, and a small amount of urine is aspirated to confirm the needle's intraluminal position.

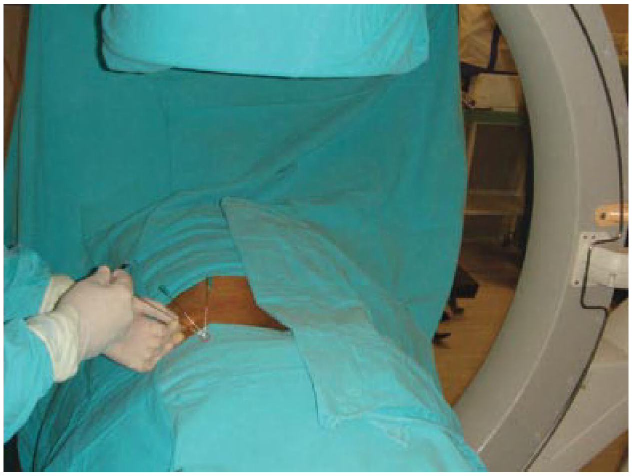

Figure 13.3 The intersection of the two lines of small needles placed in the lumbar area coincides with the desired calyx. The 18G needle is advanced under fluoroscopic control towards the point of intersection of the lines that project both intramuscular needles in order to reach the selected calyx.

Definitive puncture of the renal collecting system with an 18G diamond needle permits the immediate introduction of a 0.038-inch guidewire into the collecting system. The rigidity of this needle is advantageous for accurately directing the needle diamond tip as it is advanced through the fascial planes.

If at the point of withdrawing the trocar of the needle spontaneous output of urine has not been observed, it is advisable gently to try to introduce a hydrophilic guidewire, observing the advancement of the guidewire under fluoroscopy. Typically, it moves into the cavity of the calyx and progresses towards the renal pelvis. If for some reason the guidewire does not easily advance, it is advisable to inject an additional volume of contrast through the initially placed ureteral catheter with the intention of filling the calyx cavity and thereby facilitating the progression of the hydrophilic guidewire.

If no urine exits from the 18G needle, it is not advisable to inject contrast through the needle, since contrast can extravasate, creating a lake of radio-opaque material and making it difficult to visualize the shape of the kidney cavities. Should this occur, the procedure must either be abandoned and returned to at another time, or the urologist must wait until there has been adequate absorption of the contrast material.

In situations where the volume of the stone occupies the entire volume of the calyx selected to be punctured, the needle is advanced until there is the tactile sensation of the needle tip touching the hard surface of the stone. In this situation the tip of the trocar of the needle is in contact with the stone but the cannula of the needle is at a distance of 1–2 mm from the surface of the stone. It is advisable to then move the cannula on the trocar toward the stone until contact with the surface of the stone is felt. Then the trocar needle is removed and the hydrophilic guidewire is gently inserted into the narrow space between the urothelium of the calyx and the surface of the stone. Sometimes this allows the advancement of the guidewire to the renal pelvis, but in other situations it is only possible to locate the guidewire in the punctured calyx and attempting otherwise is risky because of the short length of the guidewire in the upper urinary tract. The guidewire is advanced carefully across the calyceal infundibulum. A 1-cm skin incision is made around the needle with a No. 10 blade, and the needle is removed. Then, in order to enlarge the defect in the lumbar fascia, a fascial incision needle can be used (No. 090070 Cook Urological). This instrument consists of an 18G needle fixed to a small, blunt, diamond-shaped blade that is passed over the puncture wire under fluoroscopic control, through the abdominal wall until it crosses the lumbar fascia. It is then withdrawn while gentle traction is placed on the puncture wire, and the tip of the blade is rotated 90° and then advanced again over the puncture wire in order to open the lumbar fascia more extensively. This action will facilitate the introduction of any of the available dilation systems.

Acute dilation of nephrostomy tracts can be performed with a variety of instruments. These instruments are inserted over a working guidewire. Because of the risk of perinephric guidewire kinking with loss of the nephrostomy tract and laceration of the renal parenchyma, all percutaneous dilator systems require fluoroscopic guidance [42–44].

The nephrostomy tract is dilated to 30F. In the serial dilation system, an 8F Teflon catheter is used as an obturator. Progressively larger dilators are then serially inserted over this guidewire and catheter combination. This additional obturator stiffness greatly reduces the risk of perinephric guidewire buckling.

With the access tract dilated, a working sheath is introduced into the collecting system under fluoroscopic guidance over the 30F dilator, which is then removed. The renal pelvis is examined nephroscopically to identify the obstructed segment of the ureteropelvic junction (UPJ) and locate the previously placed ureteral catheter. If necessary, either the ultrasonic probe or the grasping forceps are passed into the renal pelvis to clean out clots.

The catheter is grasped and brought out through the nephrostomy tract. A 0.038-inch super-stiff wire, which is a fixed core guidewire with an extra-stiff shaft and a flexible tip, is advanced through the catheter. A surgical assistant removes the ureteral catheter, leaving the guidewire in place at the urethral meatus (see Video 10.4). Once the UPJ has been bridged (i.e. the guidewire is in position from the flank through to the urethral meatus), the nephroscope is removed, and a hemostatic clamp is placed about 5 cm proximal to the distal end of

the guidewire. It is pulled through the nephrostomy tract to position the clamp near the urethral meatus. This maneuver ensures the preservation of the nephrostomy tract, so that if the access route to the kidney is accidently lost, it is easily recovered by following the guidancedescribed above. Additionally, if for some reason the procedure has to be interrupted, placement of the nephroureteral stent will allow both drainage and subsequent easy access.

Special situations: multiple access

In the treatment of complex renal lithiasis with branches in multiple calyces, it is sometimes necessary to make multiple punctures through different calyces. The multiple punctures can all be made initially, or alternatively one puncture can be made, through which most of the stone is removed and, if necessary, additional punctures can then be made.

If the planned multiple punctures are made at the beginning of surgery, the injection of contrast through the initially placed ureteral catheter facilitates visualization of all calyces and the most suitable for punctures can be chosen in accordance with the silhouette of the stone. The injection of contrast distends the upper urinary tract and this facilitates insertion of the needles into the calyces.

In contrast, if multiple punctures are made in addition to establishing a unique initial nephrostomy tract, the calyceal distention of the cavities may be hampered by the leaking of contrast that is injected by a 6F ureteral catheter through the Amplatz sheath tract nephrostomy. In this situation it is advisable to place a Foley catheter and to inflate the balloon inside the Amplatz sheath to occlude its caliber. Thereafter it is possible to inject contrast either through the ureteral catheter placed at the beginning of surgery or the Foley catheter, and to place a clamp to prevent leakage of contrast from the distended renal cavity. This maintains the distention of the calyces, facilitating additional punctures under fluoroscopic control.

Liatsikos *et al*. have described the technique of a single subcostal skin incision with multiple angular punctures to approach the superior, middle, and lower pole of the kidney for the management of staghorn calculi [45]. Singla *et al.* have evaluated the safety and efficacy of an aggressive approach to staghorn calculi using multiple-tract PCNL, and reported a greater stone clearance rate without increasing the risk of significant complications [46].

Conclusions

Percutaneous endourologic procedures require an advanced level of skill. The techniques used should be understood by those treating patients with complex renal stone disease to improve their ability to manage these often challenging clinical problems. The bullseye and triangulation methods are the most commonly used approaches, but refinements in technique and applications of new technology offer the potential for improved access with reduced patient and surgeon morbidity. Percutaneous puncture, tract dilation, and antegrade nephrostomy sheath placement into the desired calyx can be achieved rapidly and with precision when fluoroscopy is adequately used. For this reason and for patient comfort, access is best achieved in the operating room by the urologist, even in special situations like staghorn stones requiring multiple or supracostal accesses, calyceal diverticulum, and horseshoe kidneys.

CHAPTER 14
Computed Tomography for Percutaneous Renal Access

Khurshid R. Ghani, Uday Patel & Ken Anson
St George's Hospital and Medical School, London, UK

Introduction

Percutaneous nephrolithotomy (PCNL) requires a combination of preoperative planning, optimal percutaneous access, successful intrarenal navigation, and intracorporeal lithotripsy. The quality of radiologic information displayed to the surgeon is therefore crucial. An understanding of the extent of the stone burden and its relationship to the pelvicalyceal (PC) system should be demonstrated in order to optimize percutaneous access. The well-planned track should allow unhindered endoscopic navigation and maximize stone clearance with minimal morbidity [1]. The exact relationship with other operative landmarks such as the ribs and intra-abdominal organs, especially the colon, also has to be established for safe access.

In this chapter, we cover the role of computed tomography (CT) for percutaneous renal access. Multidetector row CT (MDCT) has revolutionized the radiologic evaluation of urinary tract disease [2]. Dedicated unenhanced and enhanced CT has now replaced ultrasound or contrast radiography for the diagnosis of calculi [3]. When applied to percutaneous renal access for stone surgery, CT has further advantages, such as identifying abnormal visceral anatomy or examining the relationship between pleura and access site. It can be used for planning access, guiding access, and in postprocedural follow-up. Each of these is further discussed, and in particular the technique for gaining percutaneous access using CT is described.

Percutaneous access planning for percutaneous nephrolithotomy

A detailed knowledge of calyceal and infundibular anatomy, as well as renal rotation, is mandatory for the successful percutaneous removal of renal stones. Knowledge of the intrarenal anatomy helps the endourologist choose the appropriate procedure for each patient. A posterior calyx is the most appropriate for percutaneous access; however, the position of the anterior or posterior calyces in relation to the kidney margin is not predictable. Ideally, access during PCNL should be through a calyceal fornix to reduce the risk of injury to interlobar vessels. With the patient in the prone position, the posterior calyces are more amenable to direct puncture. An anterior calyx could be entered, but this increases the risk of bleeding as the line of puncture may traverse the infundibulum [4]. Another hindrance of anterior punctures is that it can lead to difficulties in navigating the rest of the collecting system. The chosen point of entry must not only be safe, but should permit maximal inspection of the collecting system, in order to obtain full stone clearance.

Imaging

Determining which calyces are anterior or posterior using common radiologic methods, including oblique and lateral views, can be difficult. The intravenous urogram (IVU) had traditionally been used as the standard imaging investigation prior to PCNL; however, it is limited in that it produces a two-dimensional image of a complex and variant structure such as the PC system. Any three-dimensional (3D) information, such as the branching and direction of the calyces, is assumed. Ultrasound, although having advantages of being radiation free and providing realtime images is poor at detecting small stones and cannot reliably depict the anatomy of the nondistended collecting system. Orientation is also difficult and the ramifications of the

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

intracalyceal anatomy cannot be readily grasped from static ultrasound images. Currently, ultrasound is of limited value for planning PCNL, although it is of undoubted value for directing the needle for percutaneous access. Although basic 3D modeling is available on more recent machines, the quality still lags behind CT. This may change in future and PCNL planning on sonography may become feasible.

Computed tomography for planning percutaneous renal access

In comparison, CT can provide a wealth of 3D anatomic detail such that now it is the primary planning tool for PCNL. MDCT is even better than helical CT for visualizing the collecting system due to its thinner slice collimation and virtual elimination of motion artifact [2]. Currently, CT protocols for planning PCNL consist of either noncontrast or contrast-enhanced acquisitions of the collecting system, with or without 3D reconstruction.

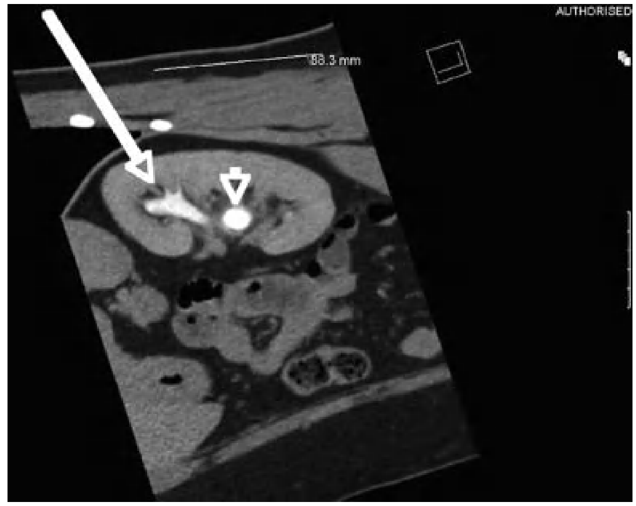

Figure 14.1 Sagittal reconstruction of a CT pyelogram study carried out to plan percutaneous nephrolithotomy access. Upper pole access (long arrow) would transgress the pleura and lung. Sagittal reconstructions are best for studying the relation between the thorax and upper renal pole (small arrow points to a pelvic calculus).

Noncontrast CT

Wickham *et al*. identified early on the advantages of noncontrast CT (NCCT) prior to renal stone surgery [5]. These included localization of peripheral stones to anterior or posterior calyces, determination of the direction of calyceal extensions of staghorn calculi, evaluation of the thickness of parenchyma overlying calculi, and visualization of low radiodensity stones poorly seen on plain radiographs. Contrast monoplanar radiography has traditionally been the standard for planning PCNL because the configuration of the collecting system cannot be established on NCCT. In comparison, the greatest strength of NCCT lies in its ability to detect even the tiniest calculi and any aberrant anatomy, especially the relationship of the kidney to the bowel and adjacent viscera.

Colonic perforation during PCNL has an incidence of 0.2–0.8%, with the left side at greater risk, especially during lower pole punctures [6]. NCCT can be used to determine the relationship between the colon and kidney, and should be routinely considered in patients with renal fusion anomalies, due to the high incidence of retrorenal colon [7]. Patients with a history of previous renal surgery, chronic colonic distention, spinal cord injury, and myelomeningocele are also more likely to have a retrorenal colon [6]. Likewise the ability to demonstrate the peritoneal reflections and overlying bowel has made NCCT the standard tool when planning access in the transplant [8] or ectopic kidney [9].

MDCT also allows image reconstruction with concomitant analysis of surrounding structures for access planning. This has limitations, in that the collecting system is not visualized and the exact position of the stones is assumed. But studies in the prone and supine positions, with sagittal reconstructions, have evaluated the risk of pleural injury during access (Figure 14.1). In patients prone and in maximal expiration, an intercostal approach between the 11th and 12th ribs would be expected to puncture the left lung in 14% and the right lung in 29% [10]. The same study demonstrated the risk of pleural injury via a supra-12th compared to a supra-11th rib approach was lower if access was in maximal expiration. In contrast, the risk of pleural injury from an upper pole supra-11th access was unaffected by the phase of respiration and prohibitively high [10].

A novel method to predict the success of fluoroscopically-guided superior pole access through an infracostal versus supracostal approach has also been described using axial NCCT [11]. CT measurements from skin to stone and stone to the first rib-free slice were used to calculate the angle required for the fluoroscopic C-arm to rotate from a supracostal to infracostal approach. In this study, an angle greater than 30° predicted failure of fluoroscopic access through a subcostal approach with a positive and negative predictive value of 100% and 76.4%, respectively.

More recent NCCT studies for planning percutaneous renal access have used 3D reconstruction techniques such as multiplanar reformatting (MPR). Using this method, any plane within the scanned volume can be recreated. One study using MPR for assessing lower pole access found that axial images overestimated the

risk of colonic injury in comparison to oblique parasagittal reformations [12]. MPR has also been used to determine extra/transpleural percutaneous upper pole access in both phases of prone respiration [13]. Using this technique, unsafe or failed access was predicted, necessitating a different approach to management in some patients. We routinely obtain unenhanced prone MPR reconstructions to determine the risk of visceral or pleural injury when planning percutaneous access.

Noncontrast 3D CT reconstruction of the staghorn calculus for planning access has also been evaluated [14–16]. In selected cases, 3D CT reconstruction of the renal stone can help determine access site and intraoperative orientation [14]. In one study, the access site was altered in a third of patients to what would have been adopted if the corresponding IVU had been used [15]. However, not all studies have concurred on the benefits of this method for access planning [16]. This may be a reflection of the limited surgical road map gained from reconstructing calculi without visualizing their location within the collecting system.

CT urography and 3D reconstruction

In contemporary practice, management of urinary tract stones relies mainly, and in some places solely, on unenhanced CT as its diagnostic accuracy is nearly perfect, but it provides no information about the PC anatomy for planning renal access. A well-chosen track is the key to successful PCNL and for this preoperative imaging should clearly demonstrate the PC system and the distribution of all relevant calculi, warn against the possibility of parallel stone-bearing calyces, and demonstrate the orientation and tightness of narrowed calyces or the neck of a calyceal diverticulum. In the case of multiple calculi or a large staghorn calculus, imaging should show the best route of access to ensure complete stone clearance. An IVU will suffice but with its anatomic and spatial accuracy, 3D reconstruction of the collecting system on contrast-enhanced CT can be more informative.

Initial studies of 3D CT for PCNL were of limited value for planning access as the stone remained indistinguishable from the contrast [17]. This limitation has now been addressed with MDCT and improvements in the CT urography (CTU) technique. In a study of 10 patients with renal calculi, 3D reformatted CTU images helped identify two patients who were unsuitable for PCNL due to challenging stone position on 3D calyceal anatomy [18]. In those patients undergoing PCNL, 3D CTU helped select the percutaneous access site. 3D CTU has also been used for planning complex access, such as in the horseshoe kidney [19]. In this particular case, a rotating 360° volume-rendered (VR) movie loop of the PC system and stone was used for planning access. VR loops make it easier to grasp spatial relationships of the calyceal and stone anatomy, and provide a clear appreciation of angle of entry along with its relationship to the ribs. These reconstructions can be uploaded onto networked computers for review in the operating room during surgery [19].

The ability of preoperative 3D CT to help plan complex PCNL has also been studied by Radecka *et al*. [20]. Plastic biomodels were created from 3D reconstructions using 16-slice MDCT. Based on subjective criteria, the 3D biomodels helped determine access points, angles of entry, and endoscopic route. However, a drawback of this technique is that unenhanced and enhanced reconstructions had to be superimposed to determine stone location within the PC system.

3D CT pyelography

For reliable 3D CT planning of renal stone surgery some requirements need to be fulfilled. First, a technique for 3D reconstruction of the PC system has to be defined which is reproducible, easy to use, and provides rapid visual appreciation of spatial and anatomic relationships. All the calyces, calyceal orientation, and angles need to be faithfully recreated. Second, for clear stone and calyceal visualization the density of the contrast in the PC system should be sufficiently high to demonstrate all the calyces but without obscuring the stone. Contrast should also be evenly distributed as dense pools may result in artifact or simulate small calculi. Stone edge should be clearly demarcated against the contrast for accurate size measurement. Lastly, the surgeon should be able to choose an appropriate reconstruction method from the different formats available to provide the necessary information for treatment planning.

The accuracy of a focused 3D CT pyelography protocol for renal calculi depiction for PCNL access planning has now been assessed [21]. In this study of 20 patients undergoing PCNL, prone 3D CT pyelography accurately demonstrated stone position and spatial relationships of the collecting system. Maximum intensity projection (MIP) reconstructions were best for calculus depiction whilst VR studies were best for collecting system anatomy. 3D CT pyelography was able to demonstrate the presence of parallel stone-bearing calyces, and display calyceal orientation and the tightness of narrowed calyces or the neck of a calyceal diverticulum [21]. The radiation burden of this 3D CT pyelography protocol (mean estimated dose 3.2 mSv) was considerably lower than that with a standard CTU protocol.

Increasingly patients with renal calculi are being diagnosed after an initial CTU investigation. Table 14.1

Table 14.1 Acquisition factors when planning percutaneous renal access using computed tomography.

Factors	Suggested option	Value in percutaneous access
Patient position	Prone	Replicates patient position for percutaneous nephrolithotomy
		Better assessment of bleeding and pleural injury risk
Respiration phase	Maximal expiration	Less risk of pleural injury, especially if supra-12th rib access
Noncontrast CT	Axial CT	Essential in transplant or ectopic kidney
		Can predict success of subcostal fluoroscopic access
	Multiplanar reformation	Assesses risk of pleura or bowel injury
CT urography/pyelography	Maximum intensity projection reconstruction	Depicts calculi in pelvicalyceal (PC) system
		Easy to produce
	Volume rendered reconstruction	Depicts PC anatomy orientation and tightness of calyces
		Helps choose access site and intrarenal endoscopic route

summarizes the factors to consider when planning percutaneous renal access using CT. Currently, 3D reconstructions are routinely obtained by 40% of uroradiologists [22]. We recommend endourologists discuss their CT reconstruction requirements with their radiologic colleagues, in order to optimize preoperative imaging and information. Figures 14.2–14.4 illustrate cases of access planning using 3D CT pyelography. An example of a 3D CT pyelography protocol for planning percutaneous renal access is provided in Table 14.2.

CT for gaining percutaneous renal access

Biplanar fluoroscopy and ultrasound, either alone or in conjunction with fluoroscopy, are the most commonly used imaging methods for gaining percutaneous renal access for PCNL [23, 24]. However, in certain scenarios, CT-guided access may be the only viable option as it provides precise cross-sectional imaging through which needle puncture of the collecting system can be achieved. This technique was first reported by Haaga *et al*. in 1977 [25].

Indications

Indications for CT-guided access include anatomic difficulties, such as spinal dysraphism [26], morbid obesity, abnormal visceral anatomy (retrorenal colon or spleen) [26], abnormal urinary tract anatomy (urinary diversion) [27], abnormal renal anatomy (multiple cysts, angiomyolipoma) [28], ectopic/transplant kidney, and failed access using standard fluoroscopy/ultrasound. The latter may occur in nondilated systems where definition of the collecting system is not feasible using retrograde (due to ureteric stricture) or intravenous contrast (due to obstruction/renal failure) administration. CT-guided access has also been used to undertake diagnostic antegrade pyelography as an alternative technique to CTU in patients with urinary tract obstruction [29].

Technique

CT-guided percutaneous renal access may be undertaken in an interventional CT suite using CT fluoroscopy [30] or using a hybrid unit that combines CT with standard fluoroscopy [31]. It can also be performed in a standard CT unit, with intermittent scans taken with the operator outside the room [32]. This last method avoids radiation exposure to the clinician but is slower. Some investigators have also used laser guidance systems to facilitate needle entry [30]. Access is obtained with the patient prone or supine–oblique. The latter can be advantageous for patients with respiratory difficulties.

A scout tomogram is initially registered to help localize scans to the renal region. A noncontrast acquisition of the abdomen is obtained and the kidneys assessed for dilation, presence of renal masses, and relative position in relation to colon, spleen, liver, and diaphragm. The collecting system should be easily discernible if dilated. If not, intravenous administration of contrast will delineate any nondilated system.

A suitable calyx for entry is identified following the principle that the safest, most direct route is through the fornix of a posterior-facing calyx. This reduces the risk of arterial hemorrhage. In comparison, infundibular or pelvic entry [33] risks transgressing the more medially placed larger arterial divisions, especially the upper pole segmental branch which courses posterior to the pelvis and upper pole infundibulum. Skin markers may be placed over the selected entry site and a further localizing scan helps reposition the marker, such that it accurately overlies the target calyx in the transverse plane [25]. Localizing scans limited to the area of interest reduce the radiation exposure. Once confirmed with the

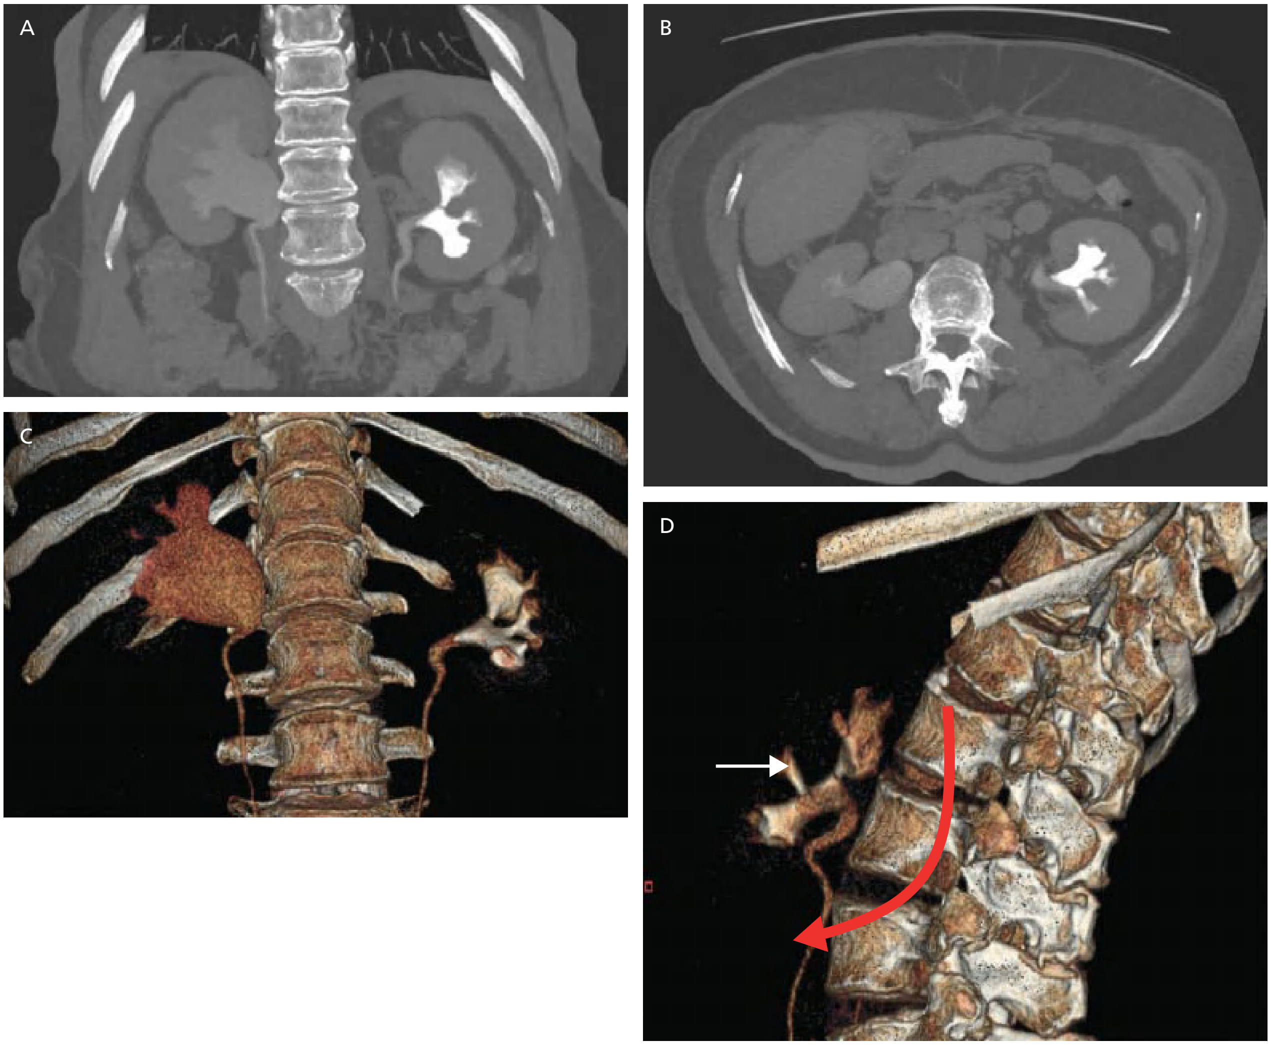

Figure 14.2 (A) Coronal and (B) axial maximum intensity projection (MIP) and (C, D) volume rendered (VR) CT reconstructions of a complete left-sided struvite staghorn calculus in a 77-year-old woman. Although the axial and coronal studies demonstrate the stone, planning of renal access is more confident with the VR studies. The lateral view (D) is taken from the movie loop and shows that the kidney has "flopped" posteriorly. Upper pole access would allow easy navigation from the upper to the lower pole (red arrow) via the renal pelvis but the lateral (interpolar) calyx (white arrow) lies at an acute angle. In planning, this may indicate a second direct puncture for stone clearance but as it is a nondependent calyx, the patient could have auxiliary shock-wave lithotripsy for retained fragments in this calyx.

transverse alignment for needle entry, the skin is sterilized and draped. After infiltration of local anesthesia, a 15-cm 18G needle with sheath (e.g. Kellett needle, Rocket Medical, Watford, Herts, UK) is advanced subcutaneously towards the target calyx. A further localizing scan with the needle in place helps finer adjustment of the needle trajectory. Based on this scan the trajectory of the needle is altered and either advanced or withdrawn until urine is obtained. Aspiration whilst withdrawing the needle may help.

Sometimes two or three localizing scans are needed for the needle to gain access to the collecting system. Often it is only necessary to advance or withdraw the needle a few millimeters to hit the target calyx. Once urine is obtained, a repeat scan confirms the position of the needle tip in the collecting system. The needle stylet is then removed and a guidewire is inserted through the plastic sheath into the collecting system. The sheath is removed and a small skin incision allows advancement of sequential dilators for tract dilation. Tract dilation may proceed using CT only, or in a standard manner with fluoroscopy and antegrade instillation of contrast. A nephrostomy tube is placed in the PC system (size 8–10F) and a further scan confirms its placement as well as excluding immediate local complications. The nephrostomy tube is sutured to the skin and the patient transferred for subsequent PCNL. Figure 14.5 demonstrates a case where CT guidance was used to access the PC system.

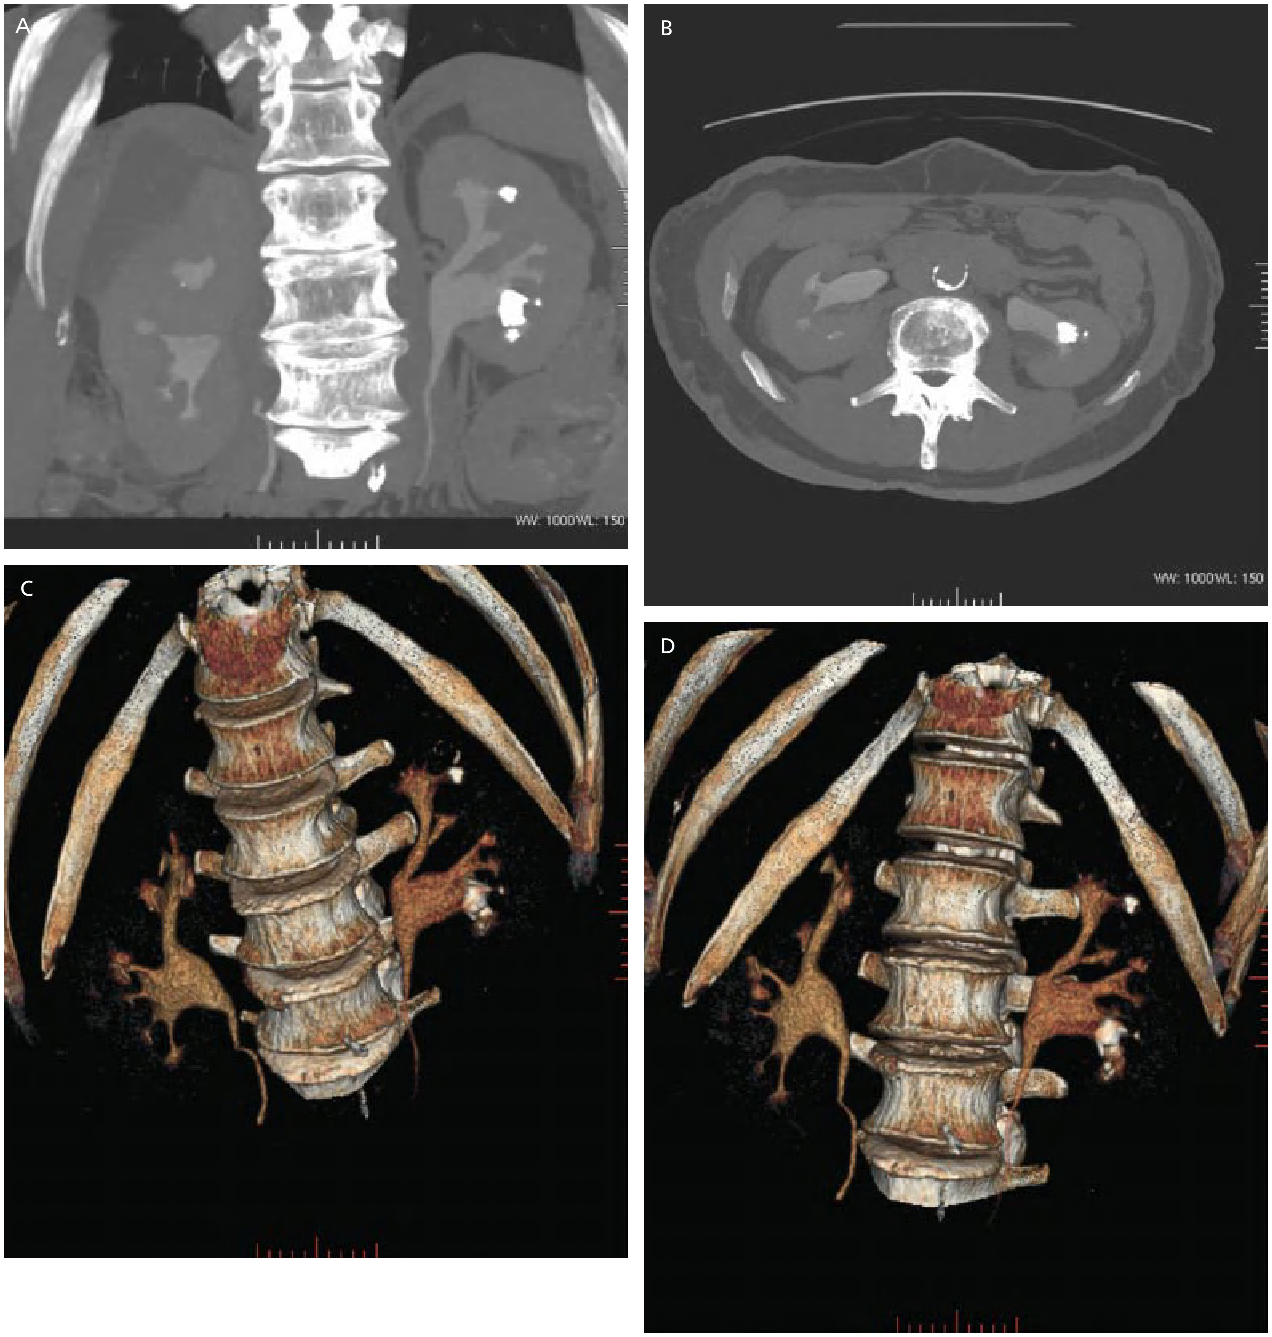

Figure 14.3 (A) Coronal and (B) axial maximum intensity projection (MIP) and (C, D) volume rendered (VR) CT reconstructions of mixed calcium stones in multiple calyces of the left kidney in a 76-year-old man. The MIP studies demonstrate all calculi well but the spatial relationships of the collecting system are only fully appreciated with the VR reconstruction. The lower pole stones lie in a relatively anteriorly placed calyx. The lower pole infundibulum is wide, but the upper pole infundibulum is narrow, and the angle between the pelvis and upper pole infundibulum is relatively acute. Furthermore, the upper pole stone lies in a narrow, laterally orientated calyx. With this knowledge a lower pole track was made, the lower pole stones removed with a 24-Fr rigid nephroscope, and the upper pole calculus removed with a 12-Fr flexible nephroscope and a wire basket. Complete stone removal was achieved with a single puncture.

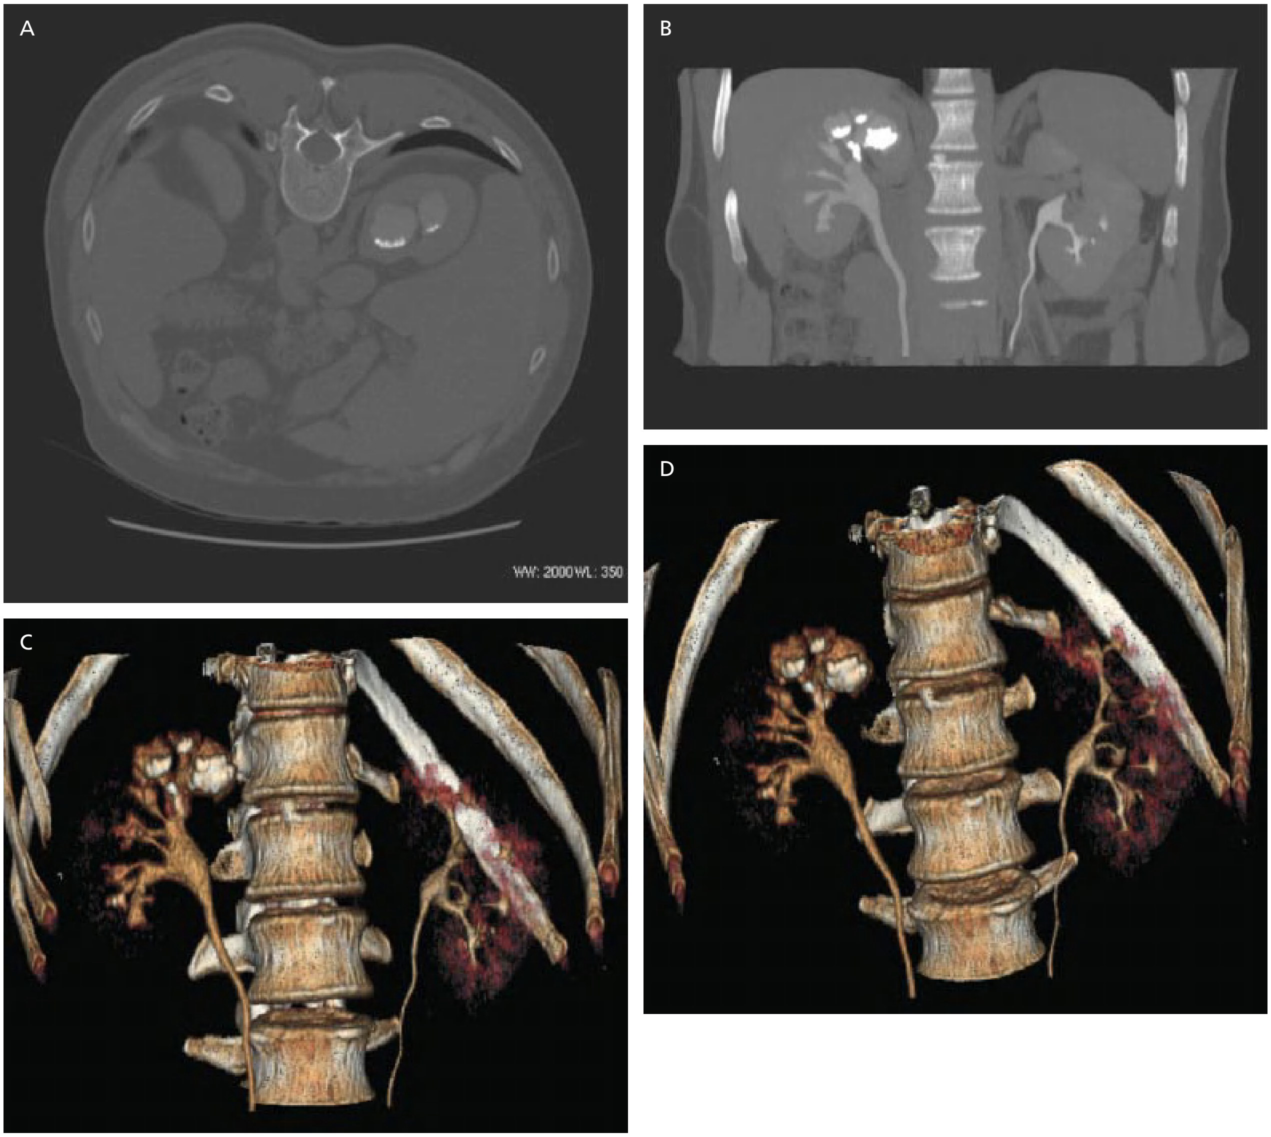

Figure 14.4 (A) Axial and (B) coronal maximum intensity projection (MIP) reconstructions and (C, D) volume rendered studies in a 67-year-old man with calcium oxalate stones in the right kidney. The obstructing fragment in the upper pole infundibulum is well seen on both the MIP or VR studies (arrow), but with the help of the VR studies, especially the movie loops, the most lateral of the stone-bearing calyces was chosen for track dilation.

Outcomes

Most studies of CT-guided access have evaluated nephrostomy tube placement for a variety of indications, including PCNL [29–32, 34, 35]. A summary of the results from large series is provided in Table 14.3. Failure of percutaneous access using CT guidance is rare and nearly all studies report 100% success rates [32–35]. Minor complications vary between 1% and 14%. However, even CT guidance does not eliminate the risk of pneumo/hydrothorax and other major complications, such as bleeding, requiring embolization [35]. Dilated PC systems are associated with a lower incidence of complications, procedural time, and need for repeat punctures [34]. In the series of six CT-guided punctures for PCNL by Matlaga *et al*. there were no access failures or complications [26]. The complete stone-free rate was 83%.

CT after percutaneous access

Following CT-guided percutaneous access an immediate scan can rule out significant procedural-related complications. Furthermore, CT can detect and correct malposition of the nephrostomy tube. Fluoroscopy in the presence of a renal pelvis perforation can lead to a

Table 14.2 3D CT pyelography protocol for planning percutaneous renal access and stone surgery [21].

*Data acquisition**
1. Administer 10 mg of intravenous furosemide **2.** Acquire contiguous noncontrast supine scans of the abdomen, 2.5-mm slice thickness, concentrating on the renal region in breath hold **3.** Combine 100 mL of iodinated contrast (e.g. Omnipaque 300 [iohexol 300 mg/mL]; Amersham Health, Bucks, UK) with 100 mL of 0.9% saline in a mechanical injector and inject intravenously into the patient at a rate of 3 ml/s **4.** Start a timer on completion of the injection and apply abdominal compression using a compression belt **5.** Rotate into prone position at 3 min, with compression maintained. **6.** Obtain an enhanced abdomen/pelvic scanogram (scout image) for repositioning and acquire a pyelographic scan of the kidneys (using the same machine settings) at 8 min **7.** Release the compression belt on completion of scanning **8.** Reconstruct noncontrast and contrast-enhanced scans at 1.25-mm intervals with 50% overlap
Image processing
Maximum intensity projection (MIP): On the workstation, images of MIP reconstructions can be viewed and saved. Enhanced MIP studies are viewed at a window level of 1000 HU and width 150 HU. Slice thickness of coronal MIP is best set at 24.6 mm **Volume rendered (VR):** VR models are produced by selecting preset thick-slab algorithms on the workstation. VR studies are reconstructed by adjusting the lower end of the voxel density threshold until the renal parenchyma is removed and the calyces seen without losing any calyceal detail (voxel density threshold usually between 115 and 135 HU) **VR movie loops:** Loops can be formatted to different magnifications, resolutions, speeds, and angles of rotation. We recommend a 360° rotating loop centered on the spine displaying the pelvicalyceal system with the lower ribs, revolving in 2° increments at a resolution of 1024 × 1024 bit

*All scans taken with a 16 × 1.25 mm configuration, pitch table speed of 27.5 mm / rotation, 120 kVp and 150–360 mAs (automatic tube current adjustment).

"white out," making manipulation of the nephrostomy tube difficult. Using CT the nephrostomy tube can be repositioned in the PC system by withdrawing the tube at the skin surface by the same distance as that between the tip of the extruded pigtail catheter and the renal pelvis [36].

The superiority of CT in assessing location (intra/extra-renal) and size of residual fragments (RFs) following renal stone surgery is established [5, 37]. Unenhanced MDCT is the gold standard for detecting RF after PCNL [38]. In a prospective analysis of antegrade pyelography, plain radiography (KUB), and NCCT after PCNL, there was a threefold reduction in completely stone-free patients if CT was used to evaluate RF status at 1 month. RFs detected on CT that were "clear" on antegrade pyelography and KUB had a mean size of 7.6 mm in 42% of patients [39]. However, a more recent study comparing noncontrast MDCT with KUB and linear tomography found no statistically significant increase in sensitivity for opaque RF greater than 5 mm [40]. This has led to the concept of the "CT clinically insignificant RF" as being less than 5 mm [40]; but this is not yet an accepted threshold. Recent work by Margaret Pearle's group has demonstrated that RF greater than 2 mm on CT after PCNL is an independent predictor of future stone-related events [41].

Conclusions

The breathtaking precision of MDCT has enhanced the power of CT for planning percutaneous renal access and stone surgery. Noncontrast reformations may raise the possibility of access-related visceral injury, necessitating an alternative access site or treatment option. 3D CT pyelography can delineate the exact location of calculi in the PC system and so help identify the most appropriate entry point for maximum stone clearance. Axial CT can be used to gain access in difficult cases. Following PCNL, CT serves as an accurate method for determining local complications as well as helping in repositioning the dislodged nephrostomy tube. Finally, the status of RFs following PCNL is best determined on unenhanced CT.

CT subjects the patient to radiation exposure, which over a lifetime can be considerable. For surgical intervention such as PCNL, the benefits of CT planning outweigh the immediate radiation concerns. Improved stone clearance would also reduce subsequent imaging. We recommend judicious use of CT and paying particular attention to those at greater risk of radiation exposure (young people, women, recurrent stone formers, particularly cystinuria patients). With the increased complexity of modern imaging, a close working relationship between the urologist and radiologist within

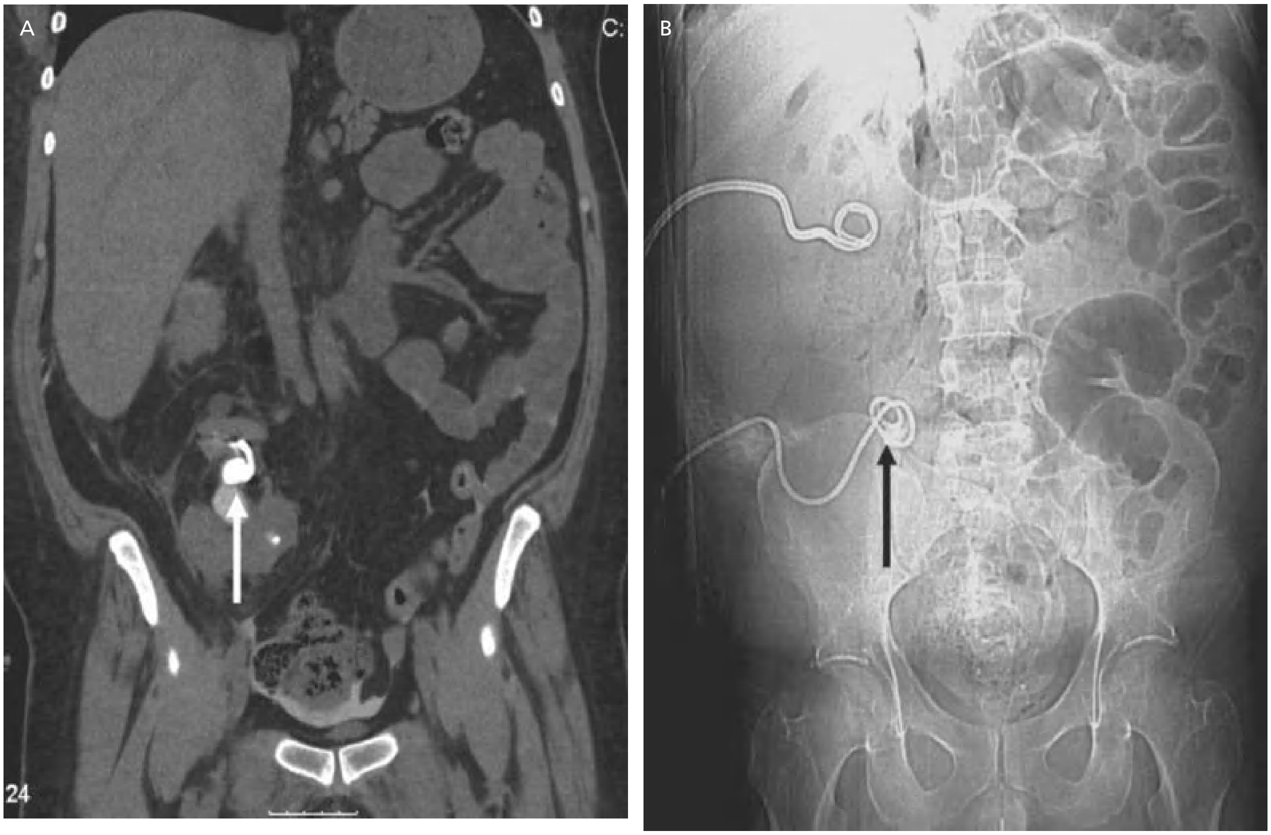

Figure 14.5 (A) Multiplanar reformatted (MPR) CT and (B) plain abdominal radiograph taken from a patient who presented with crossed fused ectopia and stones in both kidneys. The coronal CT image (A) shows a nephrostomy tube placed for access in the lower pole under CT guidance to avoid the peritoneum. The stone (arrow) is adjacent to the pigtail tip of the nephrostomy. The corresponding plain radiograph (B) shows the stone (arrow) (the stone in the orthotopic kidney has already been removed).

Table 14.3 Summary of results from CT-guided renal access studies.

Study	No. of procedures	Access failures (%)	No. of punctures	Procedural time	Complications
Le Maire *et al*. 2000 [30]	30	13	>One puncture 17%	Mean time 25 min; range 10–45	Retroperitoneal hematoma (3%), blood clot (3%), urine infection (7%), nephrostomy tube (NT) dislodgement (7%)
Barbaric *et al*. 1997 [31]	148	3	Two punctures11% Three punctures 7% Four punctures 3% Six punctures 1%	Not stated	Perinephric urine leak (5%), fever (2%), NT dislodgement (1%)
Thanos *et al*. 2006 [32]	258	0	Not stated	Range 15–50 min	Pain (14%), subcapsular hematoma (1%)
Radecka *et al*. [35]*	19	0	Not stated	Not stated	Pneumothorax (5%), bleeding requiring transfusion (5%), hydrothorax (10%), bleeding requiring embolization (5%)
Egilmez *et al*. 2007 [34]	1113	0	Two punctures 19% Three punctures 8%	Range 10–30 min	Perirenal hematoma (0.7%), frank hematuria (14%)

*Access obtained in patients undergoing PCNL only.

the endourology team allows for appropriate preoperative imaging for planning as well as for timely investigations in the management of complications.

CHAPTER 15

Endoscopic Guidance for Percutaneous Renal Access

Michael K. Louie & Elspeth M. McDougall
Department of Urology, University of California, Irvine, CA, USA

Introduction

While the methods of percutaneous access into the renal collecting system have changed since its initial description by Fernström and Johansson in 1976, their goal to create safe and direct access into the collecting system have not [1]. This chapter will detail one of these methods, the approach combining endoscopy (or ureteroscopic) and percutaneous fluoroscopy. The combined approach was first described by Grasso *et al*. in 1995 for patients with complex stone burdens and nondilated collecting systems, and obese patients who had failed prior percutaneous access using only fluoroscopic guidance [2]. While initially viewed as a salvage technique to be used for complex cases, the combined ureteroscopic and percutaneous approach offers many potential advantages to enable complete stone clearance of large stones, while the possible disadvantages of increased operating time, inability to reach the desired calyx due to an obstructing stone, or difficulty with ureteral access are minimal. Table 15.1 lists some of the potential advantages of endoscopically-guided percutaneous renal access.

Technique

Operating room preparation

The operating room is set up to allow efficient maneuvering between the affected flank of the patient and the external genitalia while the patient is in the prone position. In order to do this, the large equipment necessary for the procedure are brought into the room around the patient. These are C-arm fluoroscopy, holmium laser, lithotripsy equipment, video towers, and suction canisters. Instrumentation necessary for the procedure is listed in Table 15.2.

Patient preparation

After the induction of endotracheal general anesthesia in the supine position, patients are positioned prone with their legs abducted approximately 35° on spreader bars to allow simultaneous access to the affected flank and to the external genitalia (Figure 15.1). Leg spreader bars that are compatible with fluoroscopy are used so as to not obscure any radiographic imaging near the pelvis. The patient is in the prone position with their perineum parallel to the end of the table and the table tilted so that the respective flank is parallel to the floor; this usually requires some head-down positioning of the patient. The affected flank, external genitalia, and perineum undergo sterile preparation and draping.

Retrograde ureteral access

After positioning and sterile draping of the patient, a flexible cystoscope equipped with a 0.035-inch floppy-tip hydrophilic nitinol guidewire is placed in the bladder and the guidewire is advanced up the ureter under fluoroscopic guidance (see Video 15.1). This is usually curled gently in an upper pole calyx. The cystoscope is then disassembled and removed, being careful not to disturb the position of the guidewire in the collecting

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Table 15.1 Potential advantages of ureteroscopic guided percutaneous renal access.

Direct visual confirmation of the target calyx
Minimal attempts at percutaneous needle localization (decreased fluoroscopy time)
Visual confirmation of percutaneous needle trocar placement
Ability to secure the percutaneous antegrade guidewire for through-and-through access
Visual confirmation of renal access tract creation
Simultaneous antegrade and retrograde lithotripsy for complex or large stone burdens in difficult antegrade access areas such as the upper middle calyx
Ability to clear stone fragments proximal to the renal access sheath in a retrograde fashion
Ability to clear stone fragments within the ureter
Increased success of supracostal percutaneous access
Decreased risk of pleural complications requiring treatment

system. After removal of the cystoscope, an 8/10F coaxial dilator sheath system (Boston Scientific Corporation, Natick, MA, USA) is advanced over the guidewire, again under fluoroscopic control, to the upper pole calyx. The 0.035-inch nitinol guidewire is removed and a retrograde pyelogram is performed via either the 8- or 10F coaxial dilator sheath system (the 10F has a Luer lock-type adapter). A 0.035-inch super-stiff guidewire is then inserted via the 8F sheath and curled in the upper pole calyx. The 8F sheath is removed from within the 10F sheath, keeping the super-stiff wire and larger sheath in place, and a 0.035-inch Bentson wire is advanced via the 10F sheath up into the upper pole calyx as well. The 10F sheath is withdrawn, and the Bentson guidewire is coiled and fixed to the drapes with a hemostat clamp; this guidewire will serve as the "safety" guidewire. The super-stiff wire will be the "working" guidewire.

A 12F Foley catheter is passed into the bladder to provide bladder drainage throughout the procedure. Next, a ureteral access sheath is selected with the appropriate length and diameter. Our rule of thumb is to initially select the middle sized ureteral access sheath (9–12F internal diameter and 11–14F outside diameter); the smaller sheath is usually only used if the 8/10F coaxial sheath was difficult to place or the medium access sheath was unsuccessful. Also, the ureteroscope diameter will determine the minimum sheath internal diameter needed. If the patient has had a stent previously, then we initially select a larger sheath (12–14F internal diameter and 14–16F outside diameter). The placement of the end of the ureteral access sheath determines the length selected. For renal access, the end of the access sheath rests 1–2 cm distal to the ureteropelvic junction (UPJ) so that the ureteroscope is able to make maximal deflections within the kidney. For females, we typically will use a shorter ureteral access sheath at 35 cm, and for males, a 55-cm ureteral access sheath. There are several lengths available for the access sheath, but these work for most of the patients we encounter. The ureteral access sheath is advanced over the "working" super-stiff wire under fluoroscopic guidance, making sure not to allow buckling of the access sheath or wire within the bladder.

Table 15.2 Instrument set for endoscopy-guided percutaneous renal access.

Operating room
Fluoroscopy-compatible operating room table
Leg spreader bars
C-arm fluoroscopy with monitor
Video tower set-up with light source, camera, and monitor
Standard surgical tray (with #11 scalpel blade and Kelly clamps)
Flexible cystoscope/nephroscope (16F standard)
Flexible ureteroscope (7.5F tip and shaft if using a 9.5/11F ureteral access sheath)
Rigid nephroscope (26F offset lens)
Lithotripsy equipment and supplies including grasping forceps, stone baskets, etc.
Pressurizable warming irrigation system
Disposable
0.035-inch 150-cm nitinol hydrophilic guidewire – straight tip and/or angled tip
0.035-inch 150-cm floppy-tip Bentson guidewire
0.035-inch 145-cm super-stiff guidewire
0.035-inch 260-cm floppy-tip Bentson exchange guidewire
5F open-ended ureteral catheter
8F/10F coaxial dilator-introducer set
Ureteral access sheath
18-G 15-cm conical tip, percutaneous renal trocar needle
5-mm fascial incising needle (Cook Urological, Spencer, IN, USA)
30F nephrostomy dilating balloon catheter with 30F renal access sheath
12F Foley catheter
10 mL Luer lock syringe
Optional
Sureseal II® Side arm self-sealing adapter (Applied Medical Corp., Rancho Santa Margarita, CA, USA)

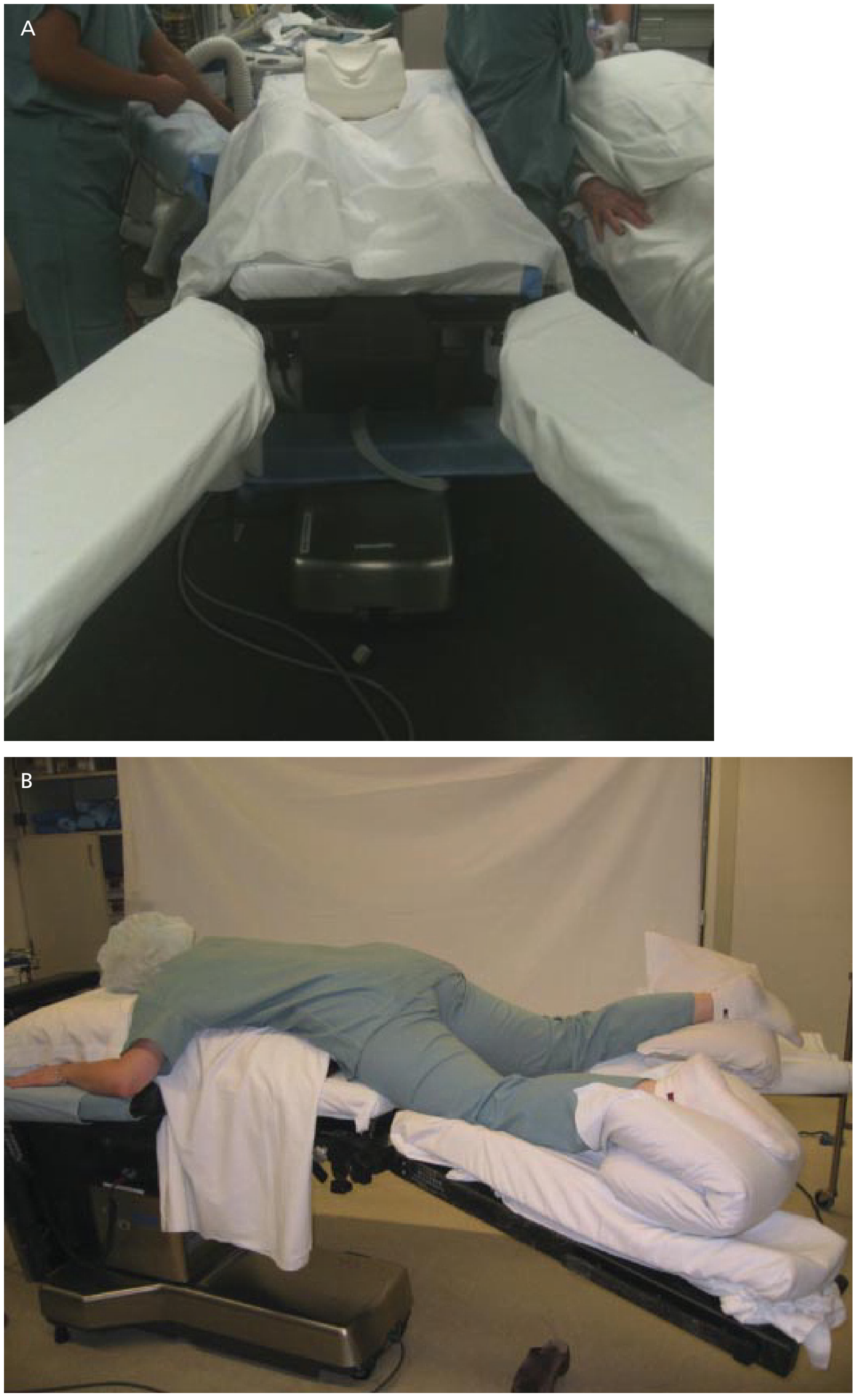

Figure 15.1 Patient positioning for endoscopic-guided percutaneous access: prone position with face and chest support, and legs on spreader bars. (A) Note the protective head support which rests on a mirror and allows the anesthesiologist access to the endotracheal tube and visualization of the patient's face during the procedure. (B) Pillows are placed under the patient's ankles to reduce strain on the peroneal nerve and the arms are in a neutral position in the "flying stance."

Percutaneous access

Once the ureteral access sheath is in position, the internal obturator of the sheath and the super-stiff wire are removed entirely. A flexible ureteroscope is advanced into the renal pelvis through the access sheath. Under fluoroscopic guidance, either air contrast or a double-contrast urogram via the ureteroscope (dilute contrast followed by 2–5 mL of air) is injected to map the calyceal system and identify the posterior calyx of choice,

because the air will naturally move to the posterior calyces with the patient in the prone position. The desired calyx usually is the most superior posterior-facing calyx. This calyx is chosen for two reasons: it provides the most direct, straight-line access to the UPJ and it requires the least amount of angulation by the nephroscope to enter the middle and lower pole calyces. In patients with the infundibulum of the desired calyx obstructed by a large calculus or stone debris, ureteroscopic holmium laser lithotripsy is performed to allow the ureteroscope to be advanced into the desired calyx.

Using a hemostat or other clamp, the target calyx is "pointed" to with the tip of the clamp under fluoroscopic control with the C-arm fluoroscope in a 90° anteroposterior position. If a rib appears to be obstructing the intended calyx, then the fluoroscope may be obliqued 5–10° in a craniocaudal fashion to create an accessible angle without interposition of the rib. A transverse skin incision of about 5 mm is made to penetrate the dermis over the target calyx. An 18G percutaneous, conical-tip, trocar needle is advanced toward the tip of the ureteroscope residing in the desired calyx, which provides a definitive radio-opaque target. The advancement of the needle is monitored fluoroscopically to position the needle hub over the tip, over the target calyx, and endoscopically to monitor the entry of the tip of the needle into the calyx with the ureteroscope. The needle is initially advanced 4–6 cm into the flank to fix its trajectory. Next, the C-arm is rotated in an arc around the patient and away from the surgeon to a 25–30° position to monitor the advancement of the needle toward the calyx and ureteroscope. The insertion of the trocar needle into the collecting system is simultaneously monitored by both fluoroscopy and direct ureteroscopic visualization. The advancement of the needle as it punctures the calyx is monitored to ensure that the needle traverses the fornix of a posterior calyx and is not inadvertently advanced too deeply. The trocar needle obturator is then removed and a 0.035-inch nitinol guidewire is passed through the needle and is directed down the ureter alongside the access sheath, or within the access sheath if the sheath is larger and therefore can accommodate both the scope and the wire. Alternatively, the nitinol guidewire can be coiled in the renal pelvis. If the nitinol guidewire is passed down the ureteral access sheath, it can be delivered out through the urethral end of the access sheath. The nitinol wire can then be exchanged for a 260-cm Bentson exchange wire using a standard 5F open-ended ureteral catheter or a Kumpe catheter. The long exchange wire allows the maintenance of access along the entire access tract from the urethra to the percutaneous puncture, and can act as the safety wire for both the renal access and the retrograde access. If the long exchange wire is in place, the ureteral access sheath can be withdrawn and passed again over a super-stiff guidewire. If the nitinol wire is passed along the side of the ureteral access sheath, an attempt is made to pass it into the bladder. In this fashion, all subsequent coaxial maneuvers on the wire will be safely passed along the natural lumen of the urinary tract. Lastly, if the nitinol wire is curled in the renal pelvis, an attempt can be made to grasp it with a stone basket or grasper via the ureteroscope and bring it out through the urethral end of the access sheath [3]. The subsequent steps in the procedure are the same as if the wire were spontaneously passed into the sheath.

Once wire access has been attained, a #11 blade is used to enlarge the transverse flank incision to 30F or approximately 1 cm. The trocar needle is removed off the wire, and a 5-mm fascial incising needle is advanced over the exchange or super-stiff guidewire parallel to the ribs and only advanced to incise the lumbodorsal fascia. The fascial dilator should not be placed over a hydrophilic coated guidewire as this can shear off the outer coating of the guidewire, leaving foreign body debris within the tract. An 8/10F coaxial dilating sheath is then passed antegrade over the guidewire just into the collecting system to facilitate passage of a second or "working" guidewire (0.035-inch super-stiff wire); this is performed under ureteroscopic vision to confirm entry into the collecting system. The 8F obturator is removed, and a 0.035-inch super-stiff floppy-tip guidewire is passed into the renal pelvis, alongside the Bentson or exchange guidewire through the 10F catheter, and coiled or passed down the ureter. At this point, if an exchange wire has not been previously placed, the initial nitinol guidewire can be exchanged for a floppy-tip Bentson guidewire, if desired, or a mosquito clamp can be secured on both ends of the nitinol guidewire to ensure this does not slip out. The 10F sheath is removed, and if the nitinol or exchange wire has not been secured for through-and-through access, then the floppy-tip guidewire is sutured to the flank to serve as a safety guidewire. Tract dilation is performed under both endoscopic vision and fluoroscopic control. A 30F dilating balloon catheter is advanced over the working guidewire until the tip of the balloon is ureteroscopically seen to be just entering the target calyx. The nephrostomy tract is then dilated by inflating the balloon under direct ureteroscopic visualization and fluoroscopic control. Once the balloon of the dilating catheter has been inflated to the manufacturer's recommended pressure with the Leveen syringe, the 30F renal access sheath is advanced over the balloon until it visually reaches the tip of the balloon. The 30F sheath is then rotated under ureteroscopic guidance until all its edges are just visible within the collecting system. This ensures the entire beveled end of the access sheath is completely within the calyx. The balloon dilator is deflated and withdrawn. At this point, if a through-and-through guidewire has not been

established, the ureteroscope can be directed into the percutaneous access sheath and an exchange wire passed through the ureteroscope and out of the percutaneous sheath. The ureteroscope can now be removed to allow maximum drainage of fragments and irrigation through the access sheath, the tip of which should be positioned at or slightly above the UPJ. The rigid or flexible nephroscope is introduced through the renal access tract and percutaneous nephrolithotripsy is performed.

Following the antegrade rigid and flexible nephrolithotripsy, and assumed removal of all the renal stone material, retrograde ureteroscopy is used to inspect the upper and middle pole calyces to ensure no stones were trapped behind the renal access sheath or positioned in an upper middle calyx not accessible by antegrade flexible nephroscopy. Any residual stone material can be managed easily in this manner with holmium laser lithotripsy and stone basketing in the standard fashion with fluoroscopic and contrast-enhanced guidance, to render the kidney stone free.

Results

Based on the initial trials of endoscopic-guided percutaneous renal access, all the urologists at our institution converted from fluoroscopic-only percutaneous access to endoscopic-assisted percutaneous access in May 2005 [4]. Sountoulides *et al*. recently reviewed our technique and results [5]. A retrospective analysis compared endoscopy-assisted percutaneous nephrolithotomy (PCNL) versus the standard, fluoroscopy-guided PCNL technique at the University of California, Irvine, CA, USA (Beck S. *et al*., unpublished data). Endoscopic-assisted PCNL (n = 51) was compared with a standard PCNL group (n = 70). All PCNLs were performed by two expert endourologists from 2002 to 2007 (n = 121). The cohorts were matched for age, body mass index, American Society of Anesthesiologists score, and stone parameters, with the average stone volume being 17 cm^3 in the endoscopic group and 16 cm^3 in the standard group. The endoscopic group was found to have less estimated blood loss (158 mL vs 211 mL, respectively, $P = .03$) and decreased postoperative transfusion rates (7.8% vs 21.4%, $P = .05$). Interestingly, the endoscopic cohort had fewer patients presenting with hydronephrosis compared to the standard group (12% vs 27%, $P = .04$). No difference was seen for intraoperative or perioperative complications, embolization rates, narcotic usage, or change in glomerular filtration rate. The endoscopic group had a slightly longer operative time compared to our standard group (227 min vs 208 min, $P = .1$). Finally, stone-free rates were similar between the endoscopic and standard groups (35% vs 46%; $P = .26$), as well as the number of patients with significant residual stone fragments (31% vs 26%, $P = .56$). "Stone free" was defined as no stone fragment on 2-mm slice CT scans of the abdomen and pelvis on postoperative day 1; significant stone fragments were considered to be 4 mm or larger.

One of the benefits to endoscopic-guided percutaneous renal access is the ease of obtaining a supracostal access tract. A recent review of the pulmonary complications from our institutional series (Khan F. *et al*., unpublished data) was compared with known complication rates in the literature. The endoscopic percutaneous access patients at our institution had significantly fewer pulmonary complications compared to those reported in the literature for fluoroscopic percutaneous access. In 111 consecutive patients who underwent endoscopic-guided percutaneous renal access at our institution, 84% required only a single puncture to obtain renal access, 93% underwent PCNL using an upper pole access, and 75% had a supracostal puncture. All patients had a postoperative chest radiograph (CXR). On CXR examination 11% had a pleural effusion, 3% a pneumothorax; and only two (1.8%) required a chest tube for clinically significant or symptomatic effusions and none for pneumothorax. In an outcomes meta-analysis for supracostal access by Lingeman *et al*., of 1580 patients underwent PCNL, 30% had supracostal access, and the overall incidence of pleural complications was 14.8% with 4.1% of these complications requiring intervention [6].

Conclusions

PCNL can be a safe and effective method for the removal of large kidney stones. Obtaining renal access from a superior renal calyx provides the most direct access to the renal pelvis, superior, middle, and lower calyces, and facilitates complete stone clearance using a single tract in most patients. Endoscopically-guided percutaneous renal access can provide single puncture, effective access to the desired calyx with minimal increase in operative time for patients undergoing PCNL for large volume upper tract renal stone disease. Our experience demonstrates the reduced pulmonary morbidity of this technique when utilized for a primarily upper pole calyx access.

CHAPTER 12
Percutaneous Renal Access Under Ultrasound Control

Mahesh R. Desai & Arvind P. Ganpule
Muljibhai Patel Urological Hospital, Nadiad, Gujarat, India

Introduction and indications for ultrasound-guided renal access

Percutaneous renal access can be achieved either with ultrasound or fluoroscopy guidance. The method of choice depends on training and personal preference. The side effects of extensive radiation during therapeutic procedures are well-known, which is the main drawback of fluoroscopy [1]. Ultrasound has several strengths as an interventional tool. It is readily available, relatively inexpensive, and portable. It has no radiation and provides guidance for access in multiple, transverse, longitudinal, and oblique planes. Its greatest advantage is use for realtime monitoring of the needle tip, which guides proper placement of the needle and avoidance of important viscera. An added advantage is that it can be used in conjunction with Doppler to avoid important vascular structures lying along the needle path.

Percutaneous ultrasound-guided access is the simplest and most direct technique to drain a hydronephrotic collecting system. It is most often utilized to place a temporary urinary diversion because of an obstructing stone or pyonephrosis .It has also been used successfully to relieve upper tract obstruction secondary to malignancy. Ultrasound-guided nephrostomy puncture is preferred for patients in whom retrograde ureteral access is unsuccessful. It is also a method of choice in pregnancy when there is a need for deobstruction. Allergies to topical or injectable local anesthetic and coagulopathy are the only relative contraindications to ultrasound-guided renal access [2].

The ultrasound-guided approach has proven to be safe and efficacious in the pediatric population [3], renal stones in transplanted kidneys [4], and pelvic renal ectopia [5].

Contemporary issues regarding ultrasound as a method to guide access are:

- Who should achieve access – urologists or radiologists?
- How should they be trained?
- Is there is any difference in the outcome for ultrasound- and fluoroscopy-guided access?
- What should be the technique of achieving access? Ultrasound versus fluoroscopy?

In this chapter, we discuss these issues in light of the existing literature. We also describe our technique of achieving percutaneous renal access with ultrasound.

Instrumentation

Types of transducers

The "transducers," or "scanning probes" as they are known, are the most important and expensive component of the ultrasound machine. The transducers emit ultrasound pulses and receive echoes during scanning. Ultrasound access requires a dedicated transducer with an ultrasound frequency ranging from 3.5 to 5.0 MHz. The monitor used for intervention should ideally be equipped with an electronic dotted line which shows the needle path. The needle guide that is attached to the ultrasound transducer helps prevent needle displacement from its proper trajectory.

Sector probes

The scans from these probes are fan shaped. These scanners can be used when the space for scanning is narrow

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

as they show a very small acoustic window, and are primarily used in gynecologic and cardiac ultrasound. They can be useful when performing nephrostomies in the pediatric age group.

Convex probes

These probes produce rectangular scans and are most commonly used for gaining percutaneous renal access.

Linear array probes:

These probes are most commonly used for scanning the breast and thyroid.

The ideal transducer for renal access is a convex transducer of 3.5 MHz, focused at 7–9 cm. If such a transducer is not available, then either a linear or sector transducer of 3.5 MHz is necessary. If children or thin patients are to be scanned, then a 5-MHz smaller transducer with a focus at 5–7 cm is required. Alternatively, a sector probe can be used in this situation (Figure 12.1).

Access needles

Using an 18G needle to access the renal collecting system helps with the introduction of a 0.035- or 0.038-inch guidewire into the collecting system. When ultrasound-guided access is to be achieved, the rigidity of the 18G needle compared to the 21G needle is advantageous for accurately directing the needle tip as it is advanced through the fascial planes. The 18G needle tip is also readily identifiable with realtime ultrasonography guidance. Although routine needles can be used for this purpose, the echo tip needle (Cook Medical Inc, Bloomington, IN, USA) is helpful in achieving ultrasound-guided access; the needle tip is scored and this increases the reflectivity and visualization on ultrasound. The needles are available in three or two parts (Figure 12.2). The three-part needle is useful for instilling contrast after ultrasound-guided puncture as the needle does not need to be removed from the puncture guide. Another variant of the needle has a Teflon sheath which allows instillation of contrast and a guidewire .

Figure 12.1 Smaller probes help in gaining access in children. The puncture guide attachment helps direct the needle.

Ultrasound technique

Orientation and calibration of the image

Before starting, it is necessary to visually check which side of the transducer produces which side of the image. Although most of the times there is an indicator on the ultrasound probe for orientation, this is best done by placing a finger at one end of the transducer and seeing where it appears on the screen; if the orientation is incorrect, the transducer should be rotated through 180°. On renal scan the liver or spleen helps in orienting the upper pole.

The machine should be calibrated properly before use and in such a way that there is a black background with white echoes [6].

Needle visualization

Clear visibility of the needle is “key” to the success of ultrasound-guided needle access (Figure 12.3). The most common reason for nonvisualization of the needle tip is nonalignment of the needle tip and transducer. This can be achieved by proper alignment. Although alignment is challenging “freehand”, it will improve with experience and occasionally a mechanical attachment can be used [7].

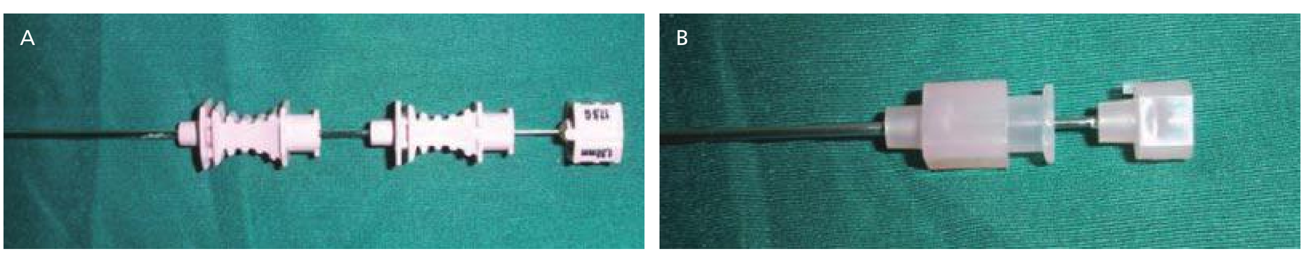

Figure 12.2 (A) Three- and (B) two-part needle.

If the needle is not visualized it may be either off centre or angled away from the transducer. A "bobbing" or "in–out jiggling" movement of the tissue in the superficial plane helps decide the path of the needle. This movement also helps push the soft tissue away from the needle path and clear visualization of the needle [7].

A few other ways in which the needle can be better visualized are by increasing the reflectivity using large caliber needles, scoring the needle tip (see above), and keeping the bevel of the needle facing upwards.

Ultrasound-guided access with a needle guide

This is the method of choice for ultrasound-guided access at our center. We use the 3.5/5-MHz probe (Profocus™, B & K Medical, Denmark) with a Doppler attachment. We typically keep one bolster under the patient's lower chest and the other at the level of the iliac crest. We consider that with the patient in the prone position and bolsters in these positions, the bowels and viscera tend to drop down, thus minimizing the chance of bowel injury.

Figure 12.3 If the needle is aligned properly, then the shaft of the needle is visualized throughout its course.

Ultrasound scanning commences posteriorly and proceeds until the posterior axiliary line. If scanned in this way, the first calyx to be seen will be the posterior calyx. The site of needle entry is marked and the puncture performed with an 18G echo tip (Cook Medical Incorporated) needle. The key point at this crucial step is that there should be minimal respiratory and ultrasound probe movement. In order to ensure an accurate puncture, the needle tip should be seen along the electronic dotted line throughout its course. The position of the needle in the desired calyx is confirmed with return of clear fluid.

The attributes of a perfect renal access are shortest possible and straight tract, traversing the skin, cortex of the kidney, and cup of the desired calyx of puncture (Figure 12.4). We consider that ultrasound-guided access maximizes the chances of this. We have been successfully performing access with ultrasound guidance in percutaneous nephrolithotomy (PCNL) with patients in the supine position; this has also been performed in the pediatric population [8, 9].

Ultrasound access without a needle guide

These ultrasound transducers do not possess an electronic dotted line or puncture guide. The operator places the probe and scans the relevant renal unit. The probable path of the needle is marked and access is gained.

Alternatively, in grossly hydronephrotic kidneys, the ultrasound probe helps with access in the paraspinal area, which is used for opacification of the pelvicalyceal

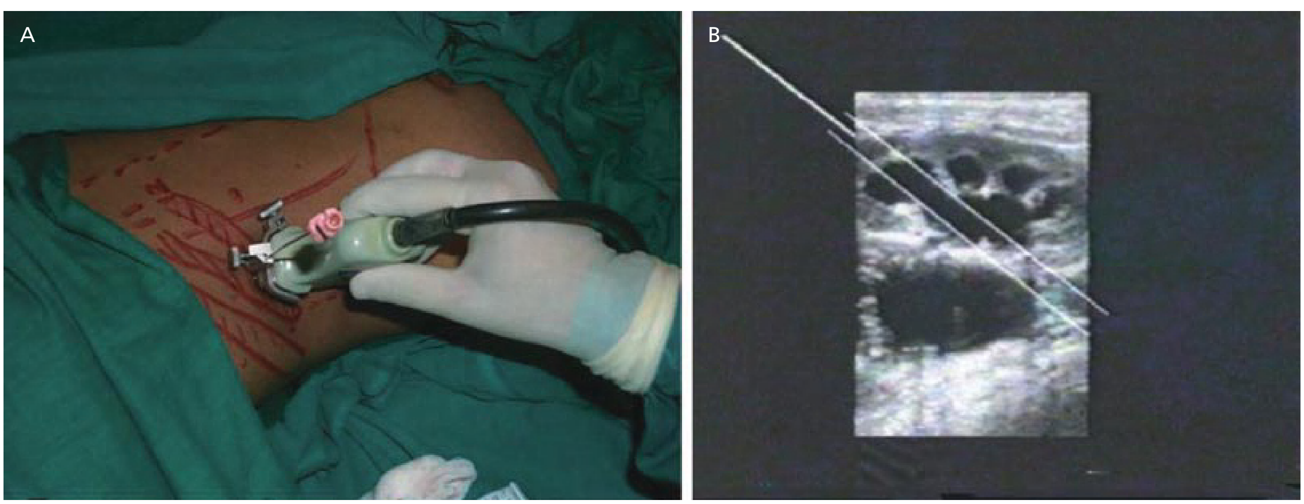

Figure 12.4 (A) The puncture guide helps in directing the needle in the desired plane and depth. (B) The ultrasound probe should be aligned in such a way that the tract provides the shortest access from the skin through the cup of the calyx, infundibulum, and finally into the pelvis.

Figure 12.5 Technique of ultrasound-guided puncture of a pelvic ectopic kidney. USG, ultrasound guided (reproduced from Desai & Jasani [5], with permission).

system and subsequent fluoroscopic–guided puncture in a appropriate calyx.

The serious limitation of the technique is that although the ultrasound probe shows the kidney and calyces, the image is devoid of depth and does not show the plane of the path that the needle traverses; as a result the chance of visceral injury increases. Ultrasound-guided puncture with a Doppler guide is of help in abnormal renal anatomy, such as horseshoe kidney and malrotated kidneys.

Application of ultrasound in special situations

The various drawbacks of PCNL in the conventional (prone) position include the need to turn the patient from the supine to prone position, risk of tube dislodgments, and neuropraxias. In addition to severe kyphoscoliosis, morbidly obese patients with heart and lung conditions do not tolerate the prone position well. Ultrasound-guided renal access is of value in such situations. Ultrasound-guided punctures are also of value in emergency situations, such as percutaneous nephrostomies in obstructive uropathy in pregnancy [8, 10].

Ultrasound punctures in ectopic kidneys and transplanted kidneys

The management of calculi in ectopic kidneys is a hotly debated topic, given that a number of treatment modalities, including laparoscopic-guided PCNL, are available. At our center we have been performing PCNL in these cases under ultrasound guidance. Preoperatively the side-to-side mobility and ability to displace the kidney in relation to the abdominal wall is assessed. The site of the puncture is the iliac fossa. A supine oblique position with a bolster under the ipsilateral hemipelvis is used. A mechanical bowel preparation with a low enema is used in all the cases. This helps in identification of gas in the sigmoid colon, which helps identify the bowel and prevents possible injury. Pressure on the ultrasound probe helps to displace the intervening bowel loops between the puncture line and targeted calyx. Similarly, contralateral pressure applied by the assistant helps displace the kidney close to the abdominal wall. All these maneuvers improve the chances of achieving a straight, short, and direct tract to the desired calyx (Figure 12.5).

PCNL is feasible in transplanted kidneys with the help of ultrasound-guided access and this decreases the amount of radiation and intravenous contrast required. With the patient in a left-sided oblique position with a bolster under the ipsilateral hip, the bowel is displaced and a puncture into the superior calyx provides easy access to the ureteropelvic junction and stone in the pelvis [4].

Preceptorship and mentoring

Competence in ultrasound-guided renal access requires a learning curve to be overcome. The mentoring should start from the residency training itself. At our center training is structured. The trainee initially performs the ultrasound in the outpatient department; later, in the first year of training, they perform ultrasound-guided percutaneous nephrostomies in grossly hydronephrotic systems, and by the end of third year ultrasound-guided punctures for PCNL for renal calculi. We believe this approach shortens the learning curve by giving the trainee insight into the intricacy of aligning the needle with the transducers.

A variety of models have been described for training in ultrasound. Hacker *et al*. have developed the biologic

model using a chicken carcass and fresh *ex vivo* porcine kidney. The laboratory model used routine PCNL equipment. For imaging, ultrasound (7.5 MHz) and a fluoroscopy unit are necessary. This model simulates realistically the clinical procedure of PCNL under ultrasound guidance. In addition, it is low cost and takes little time to prepare, and there are no legal issues involved. The drawback of this model is that it gives no tissue feel and lacks simulation of respiratory movement [11]. Mozer *et al*. described a system in which the ultrasound image was projected on fluoroscopy. The system consisted of a computer and localizer, allowing spatial localization of the position of the various instruments. Without any human intervention, the ultrasound nephrostomy tract is superimposed in realtime onto fluoroscopic images acquired in various views. In this study the possibility of fusing images derived from two imaging sources was explored [12].

Urologist or radiologist?

Many urologists do not perform percutaneous access routinely, especially in the USA and some parts of Europe. Despite evidence that urologists can safely acquire percutaneous renal access for percutaneous nephrolithotomy, many centers still rely on interventional radiologists to obtain renal access. In our opinion, the urologist is better suited for making the access. Apart from being technique oriented, their insight into the disease process helps improve outcome.

El-Assmy *et al*. studied access achieved by a urologist with that by a radiologist; both groups of patients were comparable demographically except that the group treated by the urologist had a higher risk of multiple stones and multiple tracts. The stone-free rates and complication rates were comparable. Multivariate analysis showed that bleeding was not related to whether access was performed by a urologist or radiologist. They concluded that urologists can safely and effectively obtain percutaneous renal access for percutaneous nephrolithotomy as a single-stage procedure [13]. Another study revealed that despite similar access difficulty between groups, access-related complications were less and stone-free rates were improved when a urologist acquired percutaneous access. Urologists trained in percutaneous access may be able to provide improved stone-free rates during PCNL while minimizing access-related complications [14].

To accomplish this, it is essential that the urology residency program should include training in the technique of percutaneous access, as recommended by El-Assmy *et al*. [13]. It is important to recognize that PCNL has a relatively long learning curve. The fact that kidney puncture and access is a major step for PCNL success highlights the importance of training urologists in this surgical step [15].

Ultrasound versus fluoroscopy (see also Chapter 11)

Access to the renal collecting system with fluoroscopy has the disadvantage of inability to visualize surrounding structures, such as bowel or solid organs, and need for cystoscopy and retrograde contrast instillation for opacification of the system. Percutaneous access with fluoroscopic guidance is more challenging than with ultrasound guidance [16]. The ultrasound-guided approach is safe with a very low risk of major complications. We consider ultrasound is more precise in achieving access, at times, as all the calyces are not filled on opacification.

Level 1 evidence comparing ultrasound and fluoroscopy is scant. In a clinical trial, 100 patients with no abnormality of the upper urinary tract were selected from among candidates for PCNL and randomly assigned to two 50-patient groups: ultrasound-guided access (group 1) versus fluoroscopy-guided access (group 2). Duration of the access procedure was 11 ± 3.5 min and 5.5 ± 1.7 min in groups 1 and 2, respectively ($P = .0001$). Duration of radiation exposure, on average, was 0.69 ± 0.26 min and 0.95 ± 0.44 min, respectively ($P = .0001$). They concluded that access for PCNL using ultrasound guidance is an acceptable alternative to fluoroscopy and decreases radiation hazards [17].

Zegel *et al*. compared 55 patients with ultrasound access with 33 patients with fluoroscopy access A significantly reduced number of puncture attempts was noted with ultrasound-guided access (1.2 vs 4.1) [18] , thus significantly reducing the length of time for the procedure.

In our study comparing the two methods of access, the decrease in hemoglobin and hematocrit was significantly less in the ultrasound group [3]. The number of attempts required to achieve a successful puncture was also significantly less in the ultrasound group.

Ultrasound-guided access has also been described in the nondilated system [19, 20]. The fluid infusion technique used to make the pelvicalyceal system more prominent has been described to achieve access in such situations [21]. Total ultrasound-guided PCNL has been described [22]. The authors describe that while gaining access the transducer is placed posteriorly while during dilation it is placed on the anterior abdominal wall for better visualization of the dilators. Anterior placement is possible as the patients are placed in the flank position. Although feasible, this procedure requires significant experience and the dilators must be visualized throughout the procedure to avoid under- or overdilation (Figure 12.6).

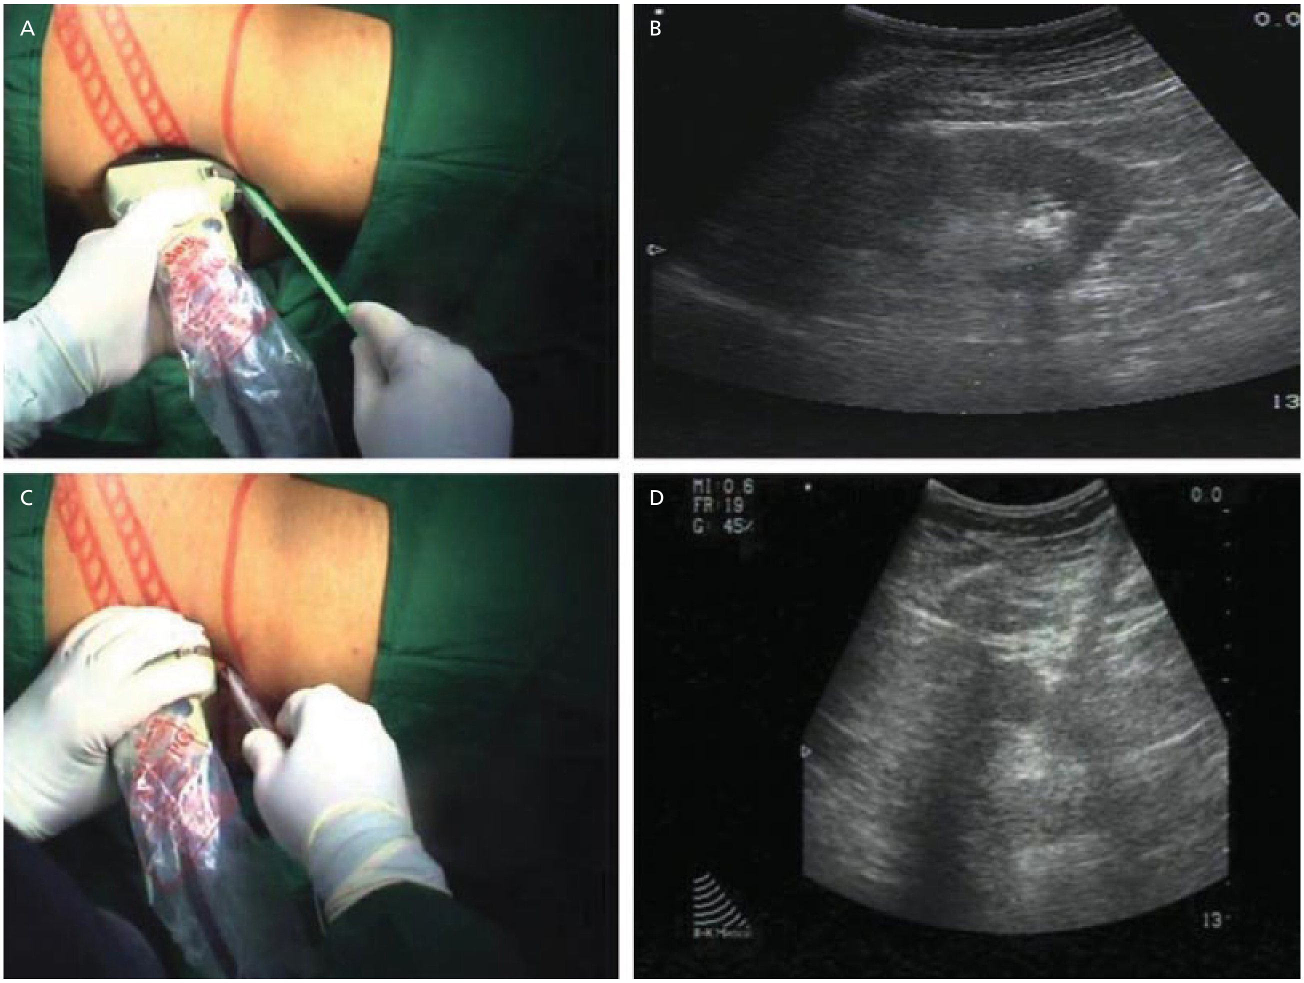

Figure 12.6 (A) Puncture is performed under ultrasound guidance. (B) The needle is visualized along the electronic dotted line. (C) The tract is dilated under realtime ultrasound guidance with a balloon dilator. (D) The balloon can be seen under realtime ultrasound guidance

Conclusions

The role of ultrasound and fluoroscopy are synergistic. Ultrasound-guided access is the method of choice in deobstruction of the upper tract in failed retrograde access, malignancy, and pregnancy. It also helps in PCNL in transplanted or ectopic kidneys. This technique requires considerable experience and training in it should be structured and begin in residency.

Introduction

Stone-free clearance and improved patient outcomes during percutaneous nephrolithotomy (PCNL) are largely dependent on the appropriate selection of the access to the kidney. While standard PCNL is often performed through a subcostal lower calyceal approach, upper calyceal access through a supracostal approach can be ideal for many clinical situations. Traditionally, concerns for increased potential perioperative complications, particularly intrathoracic, have limited utilization of supracostal access [1]. However, with a good understanding of the anatomy surrounding the upper pole of the kidney and attention to a few technical considerations during the procedure, upper calyceal access through a supracostal approach can be performed safely and efficiently. In this chapter, we describe our surgical technique for upper calyceal access during PCNL and review the outcomes of this approach in the literature.

Indications and patient selection

During upper calyceal approaches, supracostal access is performed along the long axis of the kidney. This allows for direct entry to the upper calyx and optimal visualization of the renal pelvis, ureteropelvic junction (UPJ), and upper ureter [1]. The performance of rigid nephroscopy in the direction of the long axis of the kidney minimizes the torque requirement on the kidney and results in decreased bleeding and improved clearance rates [2]. In certain circumstances, a laterally situated intercostal tract can be placed between the tips of the 11th and 12th ribs, or an infracostal approach may be used to access the upper pole (Figure 16.1). While the risk of pleural injury may be less with these techniques as compared to the more superior supracostal puncture, the benefits in visualization outside the upper pole is limited with rigid instruments and may require increased reliance on flexible endoscopy [3].

Supracostal upper calyceal access can be advantageous in several clinical situations (Table 16.1). Upper pole access can be optimal for large upper pole stones (Figure 16.2) or for complete staghorn renal calculi (Figure 16.3). Direct access to the UPJ and proximal ureter may be beneficial for treatment of large or impacted proximal ureteral calculi, particularly with concomitant renal pelvic stones, or need for antegrade endopyelotomy during UPJ obstruction management. Similarly, stones in more complicated renal systems, such as an upper pole calyceal diverticulum, or complex lower pole configurations may be more amenable to an upper calyx approach. In situations with superior kidneys located above the ribs, middle or even lower calyceal access may require a supracostal approach. Conversely, in a few patients, upper calyx puncture may be possible via a subcostal route, depending on the renal anatomy. For example, due to its incomplete ascent, horseshoe kidneys are best accessed in the upper pole [3]. However, this can usually be performed from a subcostal approach.

Anatomic considerations

A general knowledge of the anatomy of the upper pole of the kidney in relation to the surrounding structures is necessary to minimize complications during supra-

costal access to the upper calyx. The intercostal nerve and vessels are located along the inferior portion of each respective rib. Puncture sites are directed to the middle portion of the intercostal space to avoid injury to the intercostal artery and development of a hemothorax. In most situations, lateral posterior renal calyces are targeted during percutaneous access to avoid the major branches of the renal artery. Posterior calyces generally transverse Brodel's bloodless line, the avascular renal plane between the anterior and posterior divisions of the renal artery. Additionally, posterior calyces offer the shortest access path to the collecting system [3]. Needle

punctures should be directed along the axis of the renal calyx through the center of the renal papilla to avoid infundibular or renal pelvic puncture. Injury to interlobar arteries has been noted in up to 67.6% of kidneys following upper pole infundibular puncture and to retropelvic vessels in 33% following direct renal pelvic puncture [4].

The concern for intrathoracic injury following upper calyceal access is secondary to the close relationship of the upper kidney to the lungs and pleura. The upper portions of both kidneys are located anterior to the posterior portion of the 11th and 12th ribs. A review of 90 normal supine intravenous urograms during full expiration noted that 85% of upper renal calyces are located above the 12th rib [5]. In the prone position, further cephalad movement of the kidney occurs in 80% of patients [6]. Despite controlled maximal expiration, this cephalad movement results in an estimated likelihood of lung injury following supracostal access of 29% on the right side and 14% on the left [7]. The posterior diaphragm arises from the distal ends of the 11th and 12th ribs, the tip of the L1 transverse process, and the anterior aspect of the upper lumbar vertebral body [8]. During full inspiration, the posteroinferior margin of the lung expands to fill the posterior costophrenic recess. During expiration, the lung retracts and the pleura ascends cranially and laterally on the ribs [9]. The lower limit of the posterior parietal pleura crosses the 12th rib obliquely near the lateral border of the erector spinae muscles. In the midscapular line, the visceral pleura has a similar relationship at the 10th rib [10]. The initial needle puncture for a supra-12th rib access is advocated at maximal expiration and lateral to the erector spinae muscles in the 11th and 12th interspace to avoid lung and pleural injury. Supra-11th rib access can be performed in a similar fashion between the 10th and 11th rib interspace [11].

Surgical technique

Our percutaneous approach for upper calyceal access is similar to that used for the lower pole. At the onset of the procedure, the patient is placed in the dorsal lithotomy position. Using rigid cystoscopy, we place a 5F open-ended ureteral catheter to allow opacification of the renal collecting system. After subsequent placement of a Foley catheter, the patient is placed in the prone swimmer's position. A chest roll is placed horizontally to facilitate ventilation, with the neck maintained in a neutral position. An additional roll is used to slightly elevate the side of interest in order to align the posterior calyces in a more vertical position. The ipsilateral upper extremity is placed at 90° flexion, while the contralateral arm is positioned parallel to the patient. Particular attention is given to properly pad all pressure points

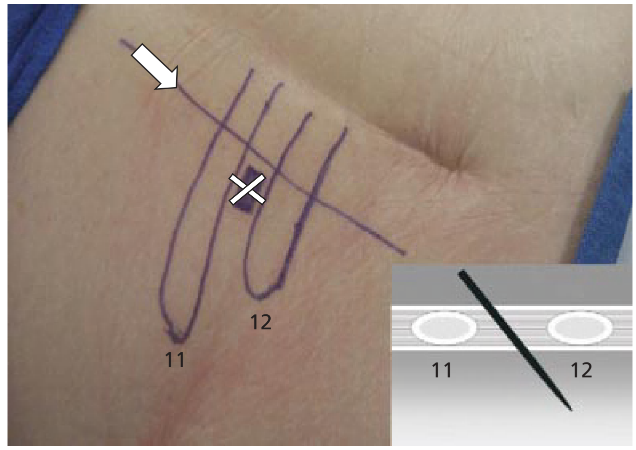

Figure 16.4 Initial puncture for a supra-12th rib approach is lateral to the erector spinae muscles (arrow) at the inferior border of the 11th rib angled towards the middle of the intercostal space (X).

and secure the patient to the table. Using biplanar fluoroscopy, we perform either the "bullseye" or "triangulation" technique for percutaneous access. The bullseye technique is described in Chapter 13 and here we will detail our supracostal approach using the triangulation technique.

Triangulation technique

For upper calyceal access, we generally prefer a puncture site within the 11th and 12th intercostal space, just lateral to the erector spinae muscles. A supra-11th rib puncture is avoided when possible. Following identification of the targeted upper pole calyx under fluoroscopy, the triangulation technique is started with an 18G diamond-tipped access needle puncture in the inferior border of the 11th rib at the skin (Figure 16.4). The needle is angled acutely so that it enters at the center of the intercostal space, thus avoiding the intercostal nerve and vessels of the 11th rib. Biplanar fluoroscopy is performed using the C-arm in two positions, anteroposterior and oblique. The anteroposterior view is along the plane parallel to the line of puncture. When the C-arm is in the anteroposterior position, adjustments to the needle position are made in the mediolateral (left–right) direction (Figure 16.5). The oblique view is obtained by rotating the C-arm through 30°. When the C-arm is positioned obliquely, adjustments to the needle position are made in the cranial–caudal (up–down) orientation with care not to drift into the mediolateral position (Figure 16.6). Ventilation is suspended in full expiration as the access needle is advanced towards the desired calyx. The C-arm is maintained in the oblique position in order to gauge the depth of puncture. After initial advancement, the C-arm is rotated back to the AP view to

Figure 16.5 Using the triangulation technique for supracostal percutaneous renal access, adjustments to the needle position are made in the mediolateral (left–right) direction when the C-arm is in the anteroposterior position (along the plane parallel to the line of puncture).

Figure 16.6 Using the triangulation technique for percutaneous renal access, adjustments to the needle position are made in the cranial–caudal (up–down) direction when the C-arm is in the oblique position (rotating the C-arm 30º).

confirm the mediolateral orientation before continuing needle movement in the oblique view. Simultaneous retrograde instillation of contrast via the open-ended catheter allows for collecting system opacification and identification.

After entry into the renal calyx, aspiration of fluid is performed to confirm the needle position in the collecting system. A 0.038-inch hydrophilic nitinol core glidewire is advanced through the access needle and manipulated down the ureter if possible. If entry to the ureter is prohibited, the wire is coiled in the renal pelvis or in the calyx that is accessible and furthest away from the calyx of puncture. An 8F fascial dilator and subsequently a 5F Cobra-tipped angiographic catheter are sequentially passed over the glidewire in order to facilitate wire positioning in the ureter. The glidewire is next exchanged for an Amplatz super-stiff wire. A second standard guidewire is placed as a safety wire into the ureter and secured to the drape following placement of an 8/10F coaxial dilator over the super-stiff wire. A NephroMax balloon is advanced over the super-stiff wire until the radio-opaque marker is noted just inside the collecting system. Following balloon inflation to 14–20 atm, the 30F Amplatz sheath is advanced over the balloon into the collecting system and standard stone treatment is performed.

Some patients, such as those with complete staghorn calculi, may require additional access into a different calyx following initial percutaneous tract placement in the upper calyx. In this situation, the Amplatz sheath is left in the upper pole while working through the second access tract in order to prevent excessive extravasation from the upper pole calyx into the pleural cavity.

At the conclusion of the procedure, fluoroscopy is performed over the ipsilateral chest and lung fields to exclude the presence of hydrothorax. In the operating room, a pigtail catheter is inserted into the chest under fluoroscopic guidance in patients noted to have significant hydrothorax or pleural effusion. Patients who are symptomatic or for whom there is concern for a hydrothorax in the postoperative period are followed with an upright chest X-ray in the recovery room and monitoring of clinical respiratory vital signs. In the postoperative period, patients with symptomatic fluid collections

are managed by tube thoracostomy. On the first postoperative day, a stone-protocol CT scan, which includes the lung bases, is performed in all patients to evaluate for residual stones.

Alternative technique

To avoid supracostal puncture, some authors have advocated a renal displacement technique. The initial placement of a sheath or dilator is performed via an interpolar renal access in order to allow for torque of the kidney downward. This can be held by an assistant while upper calyx puncture is performed via a subcostal route [12, 13]. Additionally, simultaneous fluoroscopy with retrograde flexible ureteroscopy via a ureteral access sheath has been described for endoscopically-guided percutaneous access [14]. This modification may aid in rapid and precise percutaneous puncture into the desired upper pole calyx [15].

Outcomes

Reported stone-free rates following supracostal access PCNL are comparable to infracostal approaches and range between 68% and 90% [16–23] (Table 16.2).The lack of strict criteria defining stone-free status with utilization of multiple imaging modalities may account for some of the variation in reported outcomes. Additional percutaneous access was required up to one-third of the time; this is not surprising given that complete staghorn calculi are one indication for upper pole access. Similarly, ancillary procedures, including second-look PCNL, ureteroscopy, and shock-wave lithotripsy, were performed in 3–46% of cases.

Operative complications (see also Chapters 30–32)

Overall complication rates following supracostal access during PCNL range from 10% to 26% (Table 16.3) [2, 9, 16–23]. Significant hemorrhage requiring blood transfusion or bacteremia and sepsis can occur following any PCNL procedure. Specific complications in relation to supracostal approaches are described in more detail below.

Pulmonary complications

Intrathoracic complications have been reported in approximately 1–15.3% of cases [2, 9, 16–23]. Supra-11th access, in particular, is associated with increased occurrence of pulmonary injuries. In one series, six of 26 (23.1%) supra-11th PCNLs resulted in intrathoracic complications as compared to one of 72 (1.4%) supra-12th rib accesses [2]. Hydrothorax is the most common pleural injury noted secondary to collection of irrigation fluid in the pleural space. The occurrence can be minimized with the judicious use and positioning of the Amplatz sheath to avoid leakage into the pleural space and maintenance of a low-pressure system as well as adequate renal drainage postoperatively [18]. A delayed hydrothorax may occur secondary to urine leakage through the PCNL tract to the pleura, often secondary to the formation of a renopleural fistula. Prolonged fluid accumulation in the setting of a urinary tract infection can manifest as an empyema. A hemothorax may occur following injury to the intercostal vessels during initial needle puncture. The occurrence of an isolated pneumothorax, however, is uncommon [24].

The diagnosis of pulmonary injuries can be made intraoperatively and/or postoperatively. At the conclusion of the PCNL, prone fluoroscopy of the ipsilateral lung fields should be performed in all cases involving supracostal access. A distinct fluid demarcation laterally along the chest wall from the lung or an obscured costophrenic angle warrants further evaluation or intervention if ventilation is difficult. An upright chest X-ray or computed tomography (CT) scan can be used to confirm the fluid density at the lung base in less defined cases

with high suspicion during the postoperative setting. While under anesthesia, concerning fluid collections may be aspirated during hyperventilation or treated with tube thoracostomy [25]. In the postoperative setting, a period of observation may be warranted with small fluid collections, but aspiration or tube thoracostomy connected to underwater drainage should be utilized in symptomatic patients. An evaluation by a thoracic surgeon for potential thoracotomy or video-assisted thoracoscopic surgery (VATS) may be required for nonimproving or infected pulmonary complications. In patients with ureteral stents that show delayed presentation, the effusion may be secondary to stent-related reflux and additionally treated with anticholinergics and maximal bladder decompression. Patients without ureteral stents may have delayed effusions secondary to transient obstruction from small calculi or blood clots, and require ureteral stent and Foley catheter placement [24].

Other organ injury

Though less common than pulmonary complications, injuries to adjacent organs, including the liver, spleen, and intestines, can rarely occur during upper calyceal access. A retrorenal left colon, occurring in 10% of patients in the prone position, may prohibit access to the 10th or 11th intercostal space with increased risk associated with medial punctures [26]. Additionally, a supra-11th access could puncture the liver in 14% and spleen in 33% of patients, particularly during inspiration [7]. In hemodynamically stable patients, liver injuries can often be managed conservatively with tube drainage and serial monitoring [27]. Moreover, transhepatic PCNL has been reported to be safe if necessary [28]. Splenic injuries, however, are associated with increased bleeding and may require immediate exploration and splenectomy [29]. This underscores the importance of preoperative CT imaging to determine the relationship of adjacent structures, as well as evaluation under fluoroscopy in multiple planes intraoperatively prior to needle placement in order to minimize injury to other organs [30].

Postoperative pain

While not typically quantified in most studies, supracostal access during PCNL results in increased discomfort as compared to subcostal approaches secondary to traversing of the diaphragm [20]. During needle placement, medial puncture through the paraspinal muscles is associated with increased pain and should be avoided if possible [3]. Several recommendations have been made to decrease pain following upper pole access. Intercostal nerve block has been advocated as a method to minimize supracostal tube discomfort [31]. Instead of placing a supracostal tube, a lower pole nephrostomy tube may be placed at the conclusion of the procedure via a second nondilated subcostal puncture and allowing the supracostal puncture site to close [32]. Additionally, downsizing to a small-bore percutaneous catheter at the conclusion of the procedure is associated with reduced postoperative symptoms as compared to large percutaneous catheters [33]. Tubeless supracostal PCNL has been reported with decreased need for postoperative analgesia [18, 34, 35]. Tubeless PCNL should be performed only in cases in which complete stone extraction is a near certainty. Candidates for tubeless approaches should meet strict criteria, including no collecting system perforation or significant bleeding [35]. Tubeless procedures should also be avoided in patients with concerns for magnesium ammonium phosphate stones to minimize any potential spread of infection to the chest.

Conclusions

Supracostal percutaneous access to the upper pole of the kidney during PCNL is a useful technique when optimal visualization is required for the upper calyx, UPJ, and proximal ureter. Supra-12th rib puncture should be approached lateral to the erector spinae muscles towards the superior portion of the rib during maximal expiration. Supracostal access above the 11th rib should be avoided when possible. Intraoperative fluoroscopy of the lung fields should be performed at the conclusion of the procedure, and a strong suspicion for pulmonary injuries should be maintained in the postoperative period. Patients should be counseled appropriately regarding the potential risks and complications when upper calyceal access is anticipated, particularly with regards to intrathoracic complications. However, with attention given to anatomic considerations, supracostal access to the upper pole can be obtained safely and efficiently to contribute to successful percutaneous renal surgery.

CHAPTER 17

Percutaneous Renal Access without Image Guidance

Arvin K. George & Arthur D. Smith
North Shore – Long Island Jewish Health System, The Smith Institute for Urology, New Hyde Park, NY, USA

Introduction

In 1955, Goodwin described the percutaneous placement of a needle nephrostomy for hydronephrosis, opening the door to percutaneous renal access [1]. The rapid dissemination of image-guided techniques in urology and interventional radiology has contributed to the innovation of percutaneous renal procedures. Simple drainage has evolved into percutaneous treatments for stone disease, upper tract and renal cancers, and urinary diversion/drainage, amongst others. The advancement of endourologic techniques has led urology into the minimally invasive era. This rapid innovation has forced urologists to become proficient in percutaneous renal procedures, offering optimal treatment for the expanding number of pathologies amenable to percutaneous treatment.

Indications

Percutaneous access has been described using various imaging modalities, including ultrasound and fluoroscopy [2–6]. Fortunately, there are few instances in which access must be achieved blindly. Urologists have largely been dependent upon interventional radiology colleagues for percutaneous drainage, but it is becoming an essential skill as it is the procedure of choice for renal access in the acute setting. The inability to obtain retrograde access or opacify the collecting system in a retrograde fashion may be due to previous cystectomy and urinary diversion, locally invasive prostate cancer, benign prostatic hyperplasia, urinary tract fistulas, alternate primary cancers obstructing the ureters, pelvic lipomatosis, and retroperitoneal fibrosis [7]. Renal insufficiency may preclude the use of intravenous pyelography. On rare occasions, access to various imaging modalities may be unavailable, or proficiency with image-guided percutaneous nephrostomy placement may be lacking.

Anatomy (see also Chapter 6)

The retroperitoneal location of the kidney allows for relatively safe percutaneous access via a posterior approach. Nephrostomy placement without image guidance is completed utilizing anatomic landmarks, assuming normal renal anatomy. A thorough understanding of renal anatomy and relations is essential to avoid complications and gain access to the collecting system [8].

The kidney is a mobile organ and its position can vary depending on patient position and phase of respiration. With respiratory excursion, the kidneys descend on average 4–5 cm, reaching as far as the iliac crest. Generally, the right kidney lies 1–2 cm lower than the left due to its position below the liver. The pleural reflection is posterior to the upper third of both kidneys and needle placement above the 12th rib places patients at additional risk for pneumothorax. The renal hila are directed ventromedially and are approximately 5 cm lateral from the margin for the spinous process of the L1 vertebra. The right kidney is intimately associated with the liver anteriorly and laterally, the colon anteriorly, and the duodenum and vena cava anteriorly and medially. The left kidney is intimately associated with

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

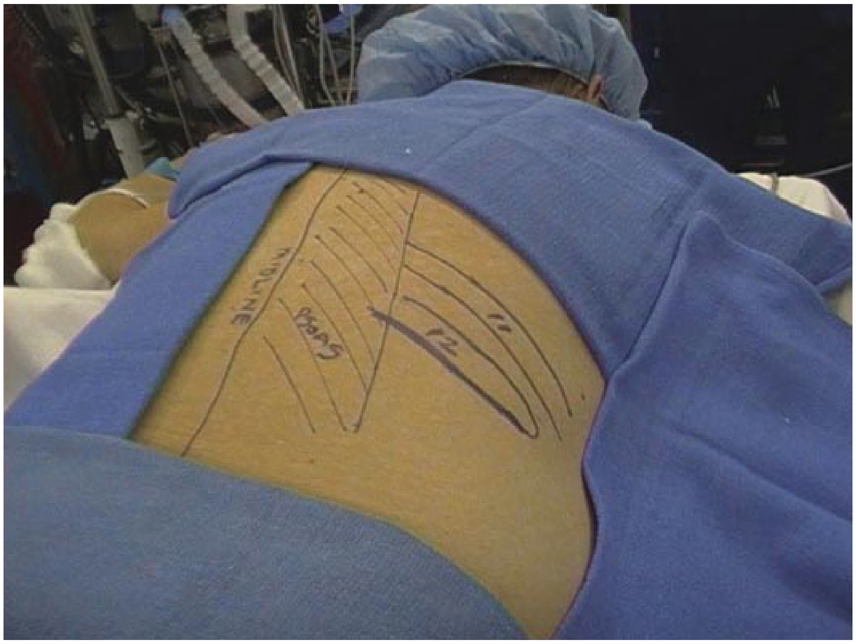

Figure 17.1 Muscular and bony relations relevant to percutaneous renal access.

the spleen laterally, colon anteriorly, and tail of the pancreas and aorta anteriorly and medially. Careful needle placement is crucial for safe nephrostomy placement and to avoid visceral organ injury.

Bony and muscular relations

The average size of each kidney is approximately 11 cm in length, 6 cm in width, and 3 cm in thickness. They lie between the 12th thoracic (T12) and 3rd lumbar (L3) vertebrae. The 11th and 12th ribs are superficial to the upper pole of the kidneys. The intercostal neurovascular bundle courses inferiorly to the corresponding rib, and should be avoided if possible (Figure 17.1).

The kidneys lie in an oblique plane abutting the psoas which directs its longitudinal axis 30° from the midline, and renders the lower poles more anterior (further from the skin surface) in the prone position. The lumbar notch has been described as a depression that can be palpated, allowing for safe placement of needle puncture [9]. The superior margin consists of the latissimus dorsi and 12th rib, is medially bounded by the sacrospinalis and quadratus lumborum muscles, and laterally by the transversus abdominus and external oblique muscles (Figure 17.2).

Vascular considerations

The renal artery arises from the aorta at the L1 level, dividing into anterior and posterior branches. The anterior branch divides into three to four segmental arterial branches which supply the anterior and polar regions. The posterior branch gives rise to one posterior segmental renal branch that supplies the posterior surface of the kidney, excluding the polar regions. The segmental arteries give rise to a variable number of interlobar arteries that divide and become the arcuate branches, which subsequently become the interlobular arteries. The interlobular arteries course peripherally in the cortex to supply the afferent arterioles of the glomeruli. Broedel's line represents a watershed zone between the distribution of the anterior and posterior divisions of the renal artery [10]. It allows for percutaneous access through a relatively avascular plane that avoids major arterial branches, potentially avoiding excessive bleeding, pseudoaneurysm formation, and development of arteriovenous malformation (Figure 17.3).

Calyceal anatomy

Calyceal architecture exhibits a considerable degree of variability. Calyces can be divided into superior, midzone (anterior and posterior), and inferior. Two types of calyceal configurations have been reported, the Broedel and Hodson types [10, 11]. The Broedel configuration describes anterior calyces as being angled medially and posterior calyces more peripherally. The Hodson configuration is in direct opposition with the anterior calyces angled laterally, and the posterior calyces more medially. Kaye and Reinke studied calyceal distribution on computed tomography (CT) imaging and determined that the Broedel type is more

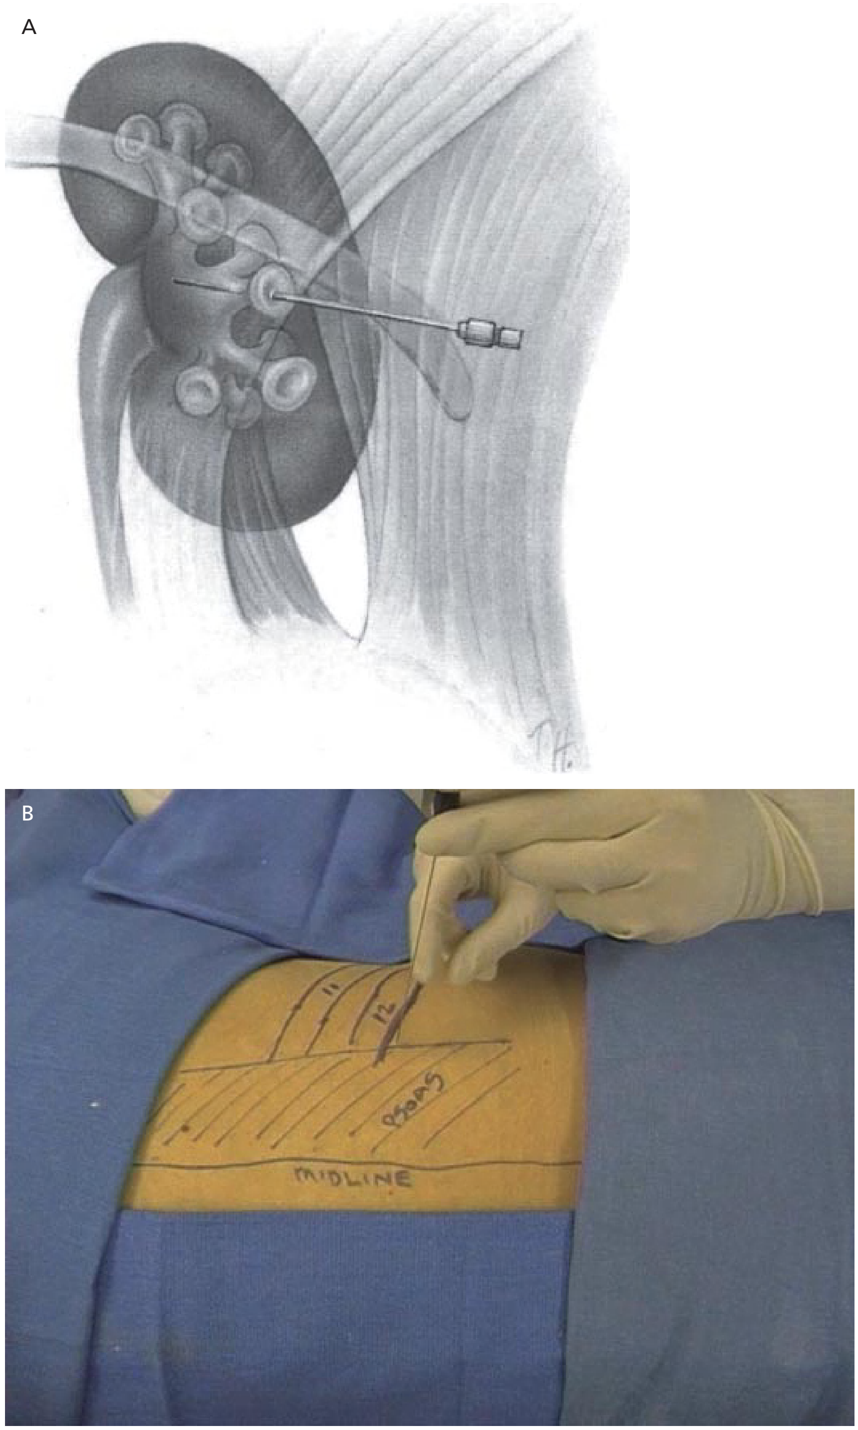

Figure 17.2 (A) Lumbar notch. The superior margin consists of the latissimus dorsi and 12th rib, is medially bounded by the sacrospinalis and quadratus lumborum muscles, and laterally by the transversus abdominus and external oblique muscles. (B) Needle puncture through lumbar notch in anatomic model.

commonly seen on the right, and the Hodson type on the left [12].

In clinical practice, emergent nephrostomy decompression without image guidance can most easily be done using a posterolateral approach to access a posterior or lower pole calyx.

Technique

Prior to proceeding, the patient should be educated on the inherent risks of percutaneous nephrostomy. The lack of image guidance places the patient at slightly greater probability of experiencing an adverse event, as

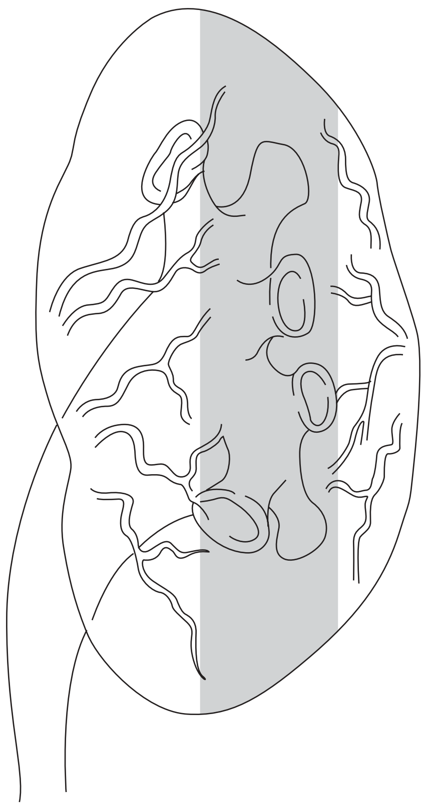

Figure 17.3 Broedel's avascular zone (shaded).

multiple passes may be required to obtain initial access. Preprocedural laboratory values are reviewed, including a coagulation profile, platelet count, and urinalysis. Preoperative broad-spectrum antibiotics are given, and narrowed according to sensitivity profiles when clinically appropriate. General anesthesia is not required in most cases, as use of a local anesthetic and sedation is usually sufficient. The patient is positioned prone with all pressure points padded. The ipsilateral flank is prepped widely, and draped with adequate exposure to facilitate choosing the site of skin puncture.

Initial skin puncture is guided by anatomic landmarks, as discussed previously. The lumbar notch can be palpated, and is an anatomic window that provides the path of least resistance when determining the ideal tract for collecting system access. The 12th rib is identified, and needle entry should be below this point to minimize the risk of pneumothorax and intercostal nerve irritation. After selection of the puncture site, the skin and subcutaneous tissues are infiltrated with local anesthetic.

An 18G sheathed access needle provides stability, can be torqued easily, and does not require exchange to place a suitable working wire. An obstructed, dilated system provides a larger target area to obtain access and can be achieved safely with the convenience of a larger needle. Alternatively, a 22G spinal needle may be used with a 0.018-inch wire for initial entry. A smaller gauge needle can diminish the risk of clinically significant hemorrhage associated with renal puncture, as well the risk of visceral organ injury [13]. The needle is positioned at the lumbar notch, oriented slightly cephalad, and angled approximately 30º in relation to the vertical axis. The needle is advanced to a depth of 4–5 cm and aspiration can confirm entrance to the collecting system. If initially unsuccessful, negative pressure is applied to the needle while being withdrawn as it may then be slowly pulled back into the collecting system. The needle can be repositioned at the same puncture site and slight modification of angle and depth will allow access to the pelvicalyceal system. Once access is confirmed with aspiration of urine, a hydrophilic atraumatic tipped guidewire is passed gently into the system, to ensure no resistance is encountered. If the initial indication for blind nephrostomy was the inability to opacify the collecting system, an antegrade pyelogram can be performed to retarget an alternate calyx if deemed necessary. In the case of obstruction causing infection, the primary goal is drainage, and which calyx is accessed becomes less relevant. The remaining steps mirror those of the standard percutaneous access. A skin incision is made, and tract dilation is performed 2–4F greater than the size of the desired nephrostomy tube. The nephrostomy tube is passed over the guidewire and deployed along the percutaneous tract in the collecting system.

Results

The blind percutaneous technique should be reserved for emergent cases in which retrograde access cannot be obtained, opacification of the collecting system is not feasible, or imaging is unavailable. Chien *et al*. reported a 98% success rate in a retrospective review of 40 blind percutaneous renal access procedures, equivalent to that of image-guided access [7]. A single procedure required ultrasound guidance to obtain successful access. No adverse events or complications were reported in their series. The majority (75%) of initial collecting system entries were at the renal pelvis with 17.5% being achieved within the kidney itself, and the remaining being obtained in the upper/lower pole. A comparison of retrograde stent placement versus nephrostomy tube insertion for obstructing calculi with evidence of clinical infection revealed no significant differences in time to clinical improvement or length of stay, although those undergoing percutaneous nephrostomy had increased perceived back pain [14].

Complications

Percutaneous renal access without image guidance theoretically places patients at increased risk of morbidity.

Bleeding complications arise when segmental or interlobar branches are injured and the incidence of severe bleeding ranges from 0% to 2.6% in published series [15]. These can be reduced by ensuring that preoperative coagulation abnormalities are addressed, 22G spinal needle placement towards Broedel's avascular plane when possible, and minimizing the number of punctures [16]. Emergent decompression is largely completed for an obstructed, potentially infected urinary tract. The incidence of septic complications ranges from 1% to 21%, and decreasing manipulation and broad-spectrum antibiotics preoperatively can reduce these events [17, 18]. The risk of pleural transgression increases with intercostal punctures, the rate of pneumothorax and effusion reaching up to 4% and 8%, respectively [19–21]. If intercostal puncture is absolutely necessary, a postoperative chest radiograph should be completed, especially when access is obtained blindly. Bowel perforation is fortunately a rare complication, reported in less than 1% of cases, and can be treated conservatively in the majority of cases [22–24]. Visceral organ injury is also rare, yet patients must be informed of this potential complication [25].

Conclusions

Blind percutaneous renal access can be performed safely, with minimal morbidity when all preoperative factors are addressed. In the appropriate setting, knowledge of this technique can provide urologists with an essential skill set to expedite management and improve patient care.

CHAPTER 18

Retrograde Access for Percutaneous Renal Surgery

Burak Turna[1] & Robert J. Stein[2]

[1]Department of Urology, Ege University School of Medicine, İzmir, Turkey

[2]Center for Laparoscopic and Robotic Surgery, Glickman Urological and Kidney Institute, Cleveland Clinic, Cleveland, OH, USA

Introduction

As percutaneous surgery has usurped the role of gold standard treatment for complex stone disease, refinement in access techniques continues to be an active area of development. Certainly access to the renal collecting system is one of the more difficult steps and comfort with access techniques provides the surgeon with the capability to address almost any challenging situation. Nevertheless, occasions do arise when anatomic considerations make access difficult or stone burden is so severe that ancillary measures may be welcome or even required.

At the time of writing of this book, flexible ureteroscopy (URS) has become a standard element in the endourologist's armamentarium in the USA and much of Europe. A large majority of studies have focused on the distinct roles for URS and percutaneous nephrolithotomy (PCNL) and have set out to define which technique is best suited for specific clinical situations. Several articles have addressed the capabilities of URS in the setting of large stone burdens [1, 2]. A large prospective randomized trial has documented a relatively low stone-free rate with URS for lower pole stones of greater than 1 cm with rigorous follow-up [3].

Instead of considering PCNL and URS independently, use of both approaches concurrently may provide a means to perform lithotripsy in complex situations. Furthermore, several groups have described routine use of this technique in order to optimize results and improve efficiency in all cases of percutaneous surgery [4–6]. In this chapter we describe perioperative considerations, surgical technique, and clinical outcomes of retrograde access for percutaneous surgery.

Development of the retrograde access technique

In 1983, two groups independently described techniques for retrograde creation of a nephrostomy tract [7, 8]. Hunter *et al*. used a 9F. outer retrograde catheter passed transurethrally to direct a catheter/needle assembly towards a desired calyx [7]. Under fluoroscopic guidance, the needle was then advanced through the calyx, renal capsule, perirenal soft tissues, and ultimately skin to establish a percutaneous tract. After dilation of the tract, the stone could be treated using a standard PCNL technique. The authors performed access successfully in 15 of 20 canine kidneys and then performed one staged clinical case under sedation. Advantages of the technique mentioned by the authors included familiarity of the anatomy for urologists, directed puncture of the desired calyx, easier access in complex cases, including obese patients and those with nondilated systems, potentially less blood loss due to puncture direction away from hilar vessels, and greater distance of the operator from the fluoroscope.

The technique of Lawson *et al*. was conceptually quite similar to Hunter's group, with differences being that a 6F steering catheter was placed through an outer 8.5F retrograde catheter to target the desired calyx [8]. After the calyx, soft tissues, and skin were punctured with a 0.017-inch sharpened stylet, a standard PCNL procedure could be performed. The prototype was

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

successfully utilized in all six porcine subjects tested and also in one clinical case. A commercial kit for this technique is available through Cook Medical (Bloomington, IN, USA).

Larger series have reported using these techniques with success rates for access and stone-free status comparable to those for antegrade techniques [6, 9]. Morrisseau and Trotter used the Lawson technique successfully in 69 of 71 procedures and the Hawkins–Hunter technique in the final two patients who had renal scarring [6].The authors used a modified lithotomy position with the ipsilateral upper body elevated 30º with padding. Effective stone treatment was achieved in 86% of patients. The authors did note a significant learning curve, with the first 40 cases lasting 125 min and the final 20 cases only 90 min. In addition, fluoroscopy time averaged 20 min for the first 40 patients and only 5 min for the final 20 patients. One patient required postoperative blood transfusion.

Leal successfully gained access using the Hawkins–Hunter technique in all but one of 85 patients [9]. Stone-free rates were 92% for uncomplicated stones and 68% for more complex stones. Eight patients required postoperative transfusions.

Despite several reports of success with the Lawson and Hawkins–Hunter techniques, there are sparse reports in the literature of their use almost 30 years following their initial description. Drawbacks that have been described include the sometimes indirect route of travel of the needle through subcutaneous soft tissue, the resulting long access tracts created, and difficulty in manipulating the catheter around obstructing stones, through stenotic infundibula, or into the lower pole [4, 10]. Due in part to these limitations and as much owing to the development of small-caliber and effective flexible ureteroscopes, the use of URS-guided retrograde PCNL has become an increasingly described technique at several centers, as will be highlighted throughout the remainder of this chapter.

Indications for retrograde ureteroscopy-guided percutaneous surgery

Indications for the retrograde approach for percutaneous surgery essentially do not differ from the standard indications for percutaneous techniques. The retrograde approach can be used in cases of complex renal stones in addition to less common scenarios such as infundibular stenosis, endopyelotomy, and percutaneous resection of upper tract urothelial cancer [10, 11].

The retrograde approach may be most useful for patients in whom difficult access is proven or suspected (Table 18.1). Prior access failure, obesity, a nondilated collecting system, large and obstructing stone burden, and infundibular stenosis are situations for which retrograde-assisted access may provide higher success rates and prove more efficient.

Table 18.1 Theoretical advantages of retrograde approach.

- Potentially less complicated for patients in whom renal access is difficult:
  - Morbidly obese
  - Challenging anatomy:
    - Hypermobile kidney
    - Nephroptosis
  - Staghorn or partial staghorn stone
  - Nondilated collecting system
- Provides access to all calyces
  - Multiple percutaneous tracts may be avoided:
    - Decreased blood loss
    - Decreased risk of pneumothorax
- May decrease fluoroscopy time
- May decrease ureteral migration of stone fragments

Our group has previously demonstrated that multiple percutaneous tracts predict greater blood loss during PCNL [11]. A retrograde approach for treatment and potential repositioning of stones in difficult-to-access calyces can reduce the number of tracts necessary to only the most involved calyx [12]. Marguet *et al*. noted that, using a retrograde technique in seven patients with full or partial staghorn stones, only one tract was necessary with a stone-free rate of 71.4% with minimal residual stone [13]. An additional benefit of the retrograde approach may be reduced fluoroscopy time, although this has not yet been confirmed through comparative analysis [10].

As a result of initial success with these techniques, several groups have documented their use routinely and not just on a selective basis [4, 5]. Nevertheless, greater costs may be involved, especially if a ureteral access sheath is used for retrograde access.

Contraindications

A relative contraindication to percutaneous surgery is urinary infection. All attempts should be made to ensure sterile urine prior to the procedure. Uncorrectable bleeding diathesis is an absolute contraindication to percutaneous surgery. For such patients URS can be considered even if a staged approach is necessary for high-volume stone disease [14]. The retrograde approach is contraindicated in patients with prior urinary diversion with ileal conduit, heterotopic, or orthotopic diversion, and antegrade access with intravenous contrast instillation or ultrasound guidance is preferred.

Preoperative preparation

Proper preoperative imaging includes computed tomography (CT) for comprehensive evaluation of stone

size, position, probable composition, degree of hydronephrosis, presence of gas within the collecting system, and surrounding anatomy. Evaluation of the CT characteristics aids in selection of the preferred calyx for access. Presence of severe renal atrophy should prompt acquisition of a radionuclide renal scan to determine differential renal function. If stone size is large and renal function is poor, the option of simple nephrectomy can be entertained. A comprehensive discussion with the patient, including risks, benefits, and alternatives, should be undertaken and consent obtained.

Preoperative laboratory evaluation should include baseline renal function, blood count, platelets, and coagulation factors. A type and screen should also be obtained. Antiplatelet agents should be discontinued at least 7 days prior to the procedure and heparin or low molecular weight heparin can be substituted preoperatively for warfarin. A urine culture should be obtained preoperatively and, if positive, sensitivity-specific antibiotics should be administered. Repeat urine culture should ensure sterile urine. If sterile urine is present, prophylactic antimicrobial coverage should be administered prior to anesthesia and continued perioperatively.

Table 18.2 Instrumentation required for retrograde ureteroscopy-guided percutaneous surgery.

Instrument/disposable	Quantity
Flexible cystoscope	1
7.5F flexible ureteroscope	1
27F rigid nephroscope	1
0.038-inch Glidewire	3
Amplatz super-stiff guidewire	1
Cystoscopic camera	1–2
Light cord	1–2
Pressure bag/saline irrigation	1
Video tower	1–2
Nitinol stone basket	1
Holmium:YAG laser	Optional
200-µm holmium laser fiber	Optional
10F Dual-lumen ureteral catheter	1
9.5F/11.5F Cook Flexor ureteral access sheath	1
18G percutaneous access needle	1
8/10F coaxial dilator	1
C-arm fluoroscope	1
30F dilating balloon/nephroscopic sheath	1
Ultrasonic lithotripter	1
Nephroscopic grasping forceps	1
26-cm double-J ureteral stent	1
Nephrostomy tube	Optional

Patient positioning

The patient is initially administered general anesthesia and intubated on the transport cart. The patient is then placed in the prone position on a radiotranslucent table with bilateral chest rolls and preferably equipped with spreader bars for the legs. If spreader bars are not available, the patient's legs can be gently spread during positioning with retrograde access still achievable, though slightly more cumbersome. All pressure points are padded and the flank and genitalia are prepped prior to draping.

Procedure

The instrumentation required for the procedure is listed in Table 18.2 (see Video 18.1). Initially a flexible cystoscope is passed transurethrally and used to place a 0.038-inch hydrophilic glidewire to the ipsilateral renal collecting system. Position is confirmed using fluoroscopy. A 10F Dual-lumen ureteral catheter is then advanced over the glidewire to the mid ureter under fluoroscopic guidance. A retrograde pyelogram using the second port of the catheter defines collecting system anatomy and a second 0.038-inch glidewire is passed through the catheter, thus providing two wires in the ipsilateral ureter. After removing the dual-lumen catheter, an 11.5F outer diameter ureteral access sheath (Flexor, Cook Medical, Bloomington, IN, USA) is advanced under fluoroscopic guidance over the wire to the proximal ureter (Figure 18.1).

A 7.5F flexible ureteroscope is advanced through the ureteral access sheath into the renal collecting system (Figure 18.2). A pressure bag with saline solution is used for ureteroscopic irrigation. If ureteral stones are noted on preoperative imaging, these can be addressed ureteroscopically using holmium laser lithotripsy followed by advancement of the scope further proximally.

Depending upon the size and distribution of the stone components, several approaches can be taken once the ureteroscope is within the collecting system. If there is significant stone burden outside of the renal pelvis and calyx to be targeted for access, the ureteroscope may be advanced to these peripheral stones and laser lithotripsy can be used to fragment the stones *in situ*. Furthermore, a nitinol basket can be used through the ureteroscope to reposition the stones in an accessible area for the ensuing nephroscopy. In cases of infundibular stenosis, laser infundibulotomy is used to gain access to the dilated calyx.

When no further ureteroscopic intervention is desired, the ureteroscope is advanced to the calyx to be targeted for access (Figure 18.3). Under direct ureteroscopic as well as fluoroscopic guidance, a disposable 18G access needle is advanced percutaneously into the calyx of choice (Figure 18.4). Our technique for access involves targeting the preferred site in anteroposterior as well as oblique planes. Needle placement is confirmed ureteroscopically and a 0.038-inch glidewire is advanced into the calyx.

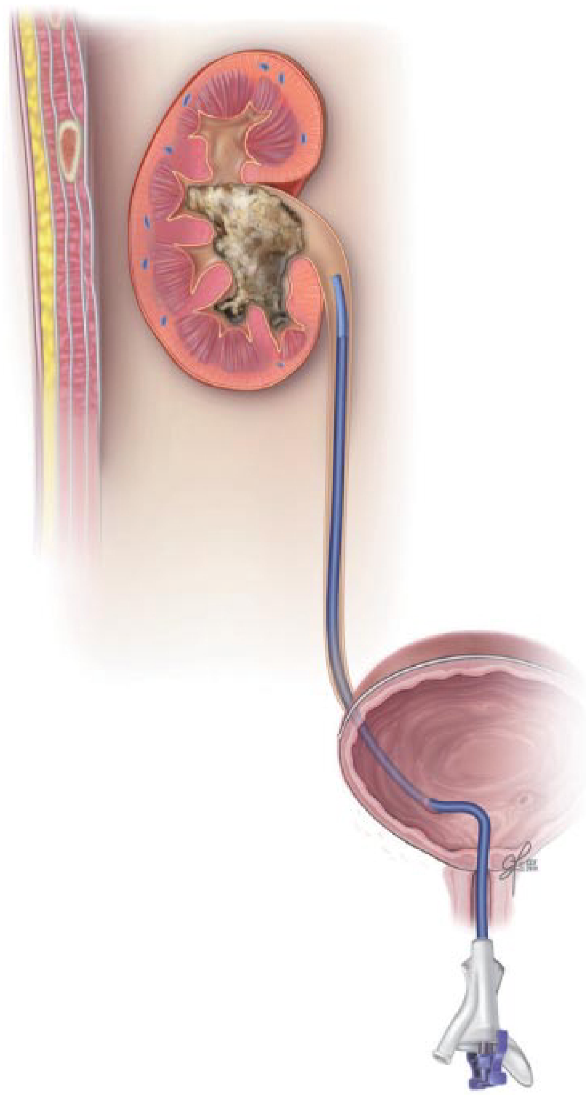

Figure 18.1 Positioning of ureteral access sheath (reproduced courtesy of the Cleveland Clinic Center for Medical Art & Photography © 2010. All rights reserved).

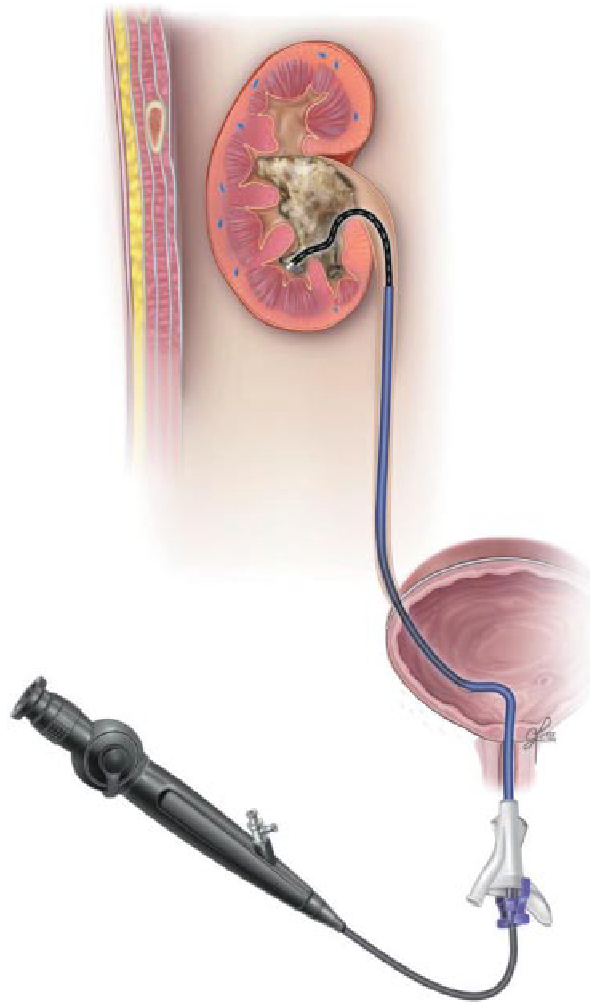

Figure 18.2 Positioning of ureteroscope (reproduced courtesy of the Cleveland Clinic Center for Medical Art & Photography © 2010. All rights reserved).

Upon identification of the wire, a nitinol stone basket is advanced through the ureteroscope, and used to grasp the wire and bring it down through the access sheath and out of the urethra for through-and-through access (Figure 18.5). If the wire is dropped by the basket within the access sheath, it usually can be advanced easily in the antegrade direction by simply pushing the wire through the access needle.

At this point the skin is incised sharply and amply around the cutaneous entry point, and the access needle is removed. An 8/10F coaxial dilator is then passed over the percutaneous wire to the proximal ureter and used to place an Amplatz super-stiff guidewire as a second wire. A 30F dilating balloon with a 30F nephroscopic sheath backloaded is then advanced into the collecting system, and used to dilate and place a nephroscopic sheath (Figure 18.6).

A 27F rigid nephroscope is then advanced into the collecting system and the stones are treated with a combination of ultrasonic lithotripsy as well as intact fragment removal (Figure 18.7). Flexible URS can be used during or following nephroscopy in order to aid in lithotripsy as well as ensure stone-free status in difficult-to-access calyces. This may limit the number of access tracts needed.

Following PCNL a 0.038-inch glidewire may be placed either in an antegrade or retrograde manner through the nephroscope and down the ureter. The access sheath is removed, the distal portion of the wire is curled in the bladder, and a 26-cm double-J ureteral stent is advanced through the nephroscope and positioned appropriately.

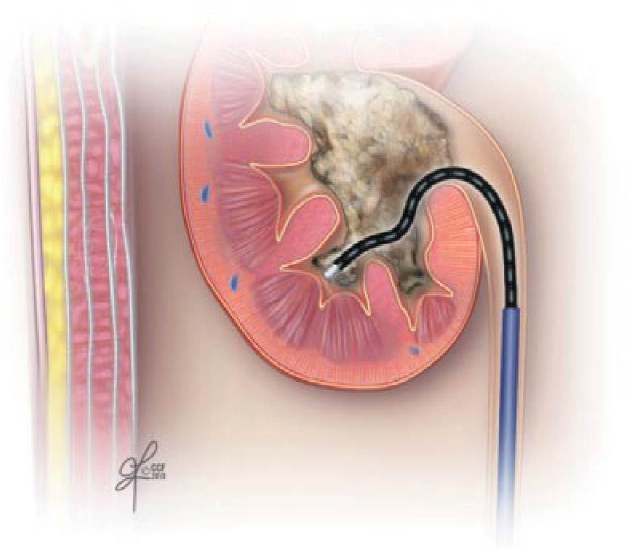

Figure 18.3 Ureteroscopic visualization of targeted calyx (reproduced courtesy of the Cleveland Clinic Center for Medical Art & Photography © 2010. All rights reserved).

Depending upon the ease of the procedure as well as the confidence in a stone-free status, a nephrostomy tube can be placed.

Special considerations

One of the greatest challenges when using the retrograde approach is the need to perform retrograde endoscopy in the prone position. Supine PCNL as originally described by Valdivia (see Chapter 10) will place the patient in a more familiar position for urologists to perform retrograde maneuvers [15]. Furthermore, the Galdakao-modified Valdivia position allows the patient's legs to be strategically placed within stirrups to provide even greater access with a retrograde technique [16]. Scoffone *et al*. described their experience with 127 patients using the Galdakao-modified Valdivia position [5]. The stone-free rate was 81.9% with an average operative time of only 70 min, and 98.4% of patients required only one percutaneous tract. The authors site many potential advantages of the supine approach besides easier retrograde access, including anesthesia considerations and likely decreased fluoroscopy exposure.

Postoperative care

Directly postoperatively, routine labwork, including hemoglobin, is obtained and a chest X-ray is performed, especially in cases of supracostal access. We routinely obtain a noncontrast CT 1 day postoperatively in order

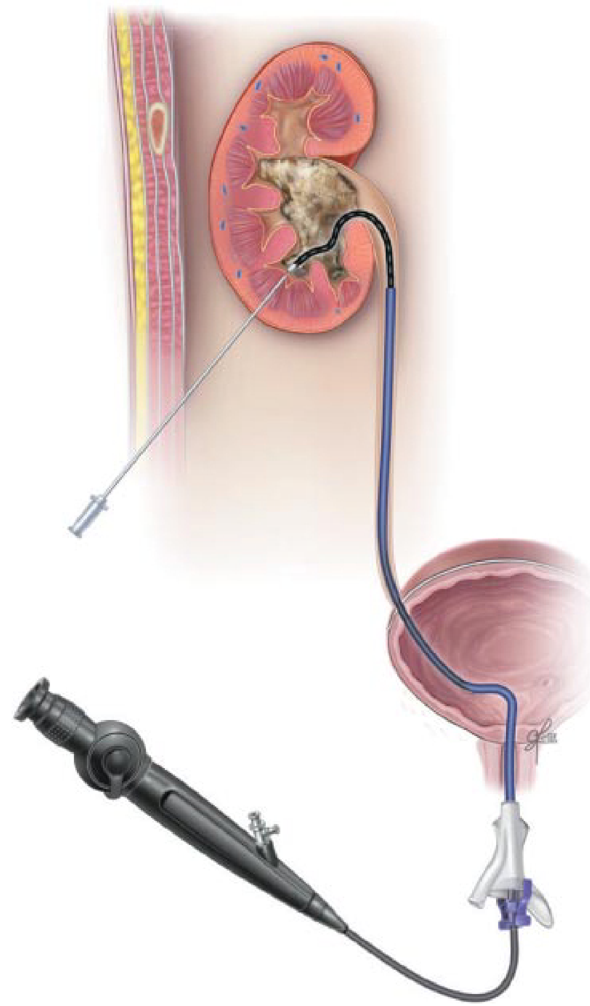

Figure 18.4 Access needle puncture under ureteroscopic guidance (reproduced courtesy of the Cleveland Clinic Center for Medical Art & Photography © 2010. All rights reserved).

to assess for residual stones. If stones are present, it is dependent on the patient's and clinician's preference whether an immediate second-look procedure is performed, especially if a nephrostomy tube has been left, or whether a delayed ureteroscopy is chosen. After performing the retrograde technique, our preference is to leave the double-J stent for approximately 1 week and then to remove the stent using flexible cystoscopy in the outpatient clinic. Warfarin or antiplatelet therapy may be resumed as early as 5 days following surgery if necessary [17].

Outcomes

Results in the literature concerning retrograde URS-guided percutaneous surgery are summarized in Table 18.3 [4, 5, 10, 13, 18, 19]. Over the last 15 years several series have been published with most describing small

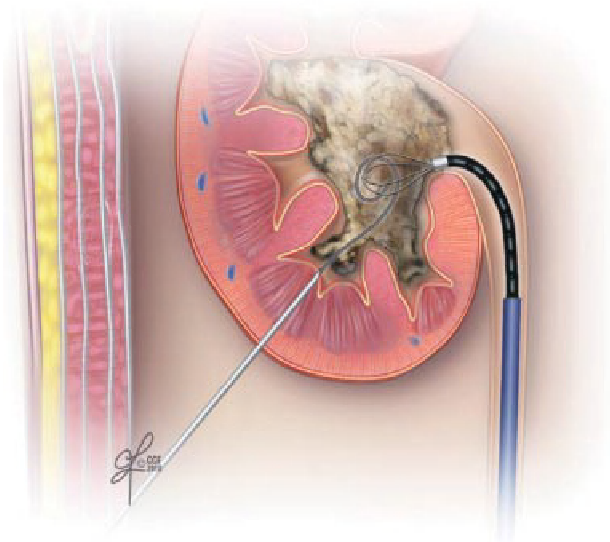

Figure 18.5 Passage of a glidewire via the access needle with basket retrieval using the ureteroscope (reproduced courtesy of the Cleveland Clinic Center for Medical Art & Photography © 2010. All rights reserved).

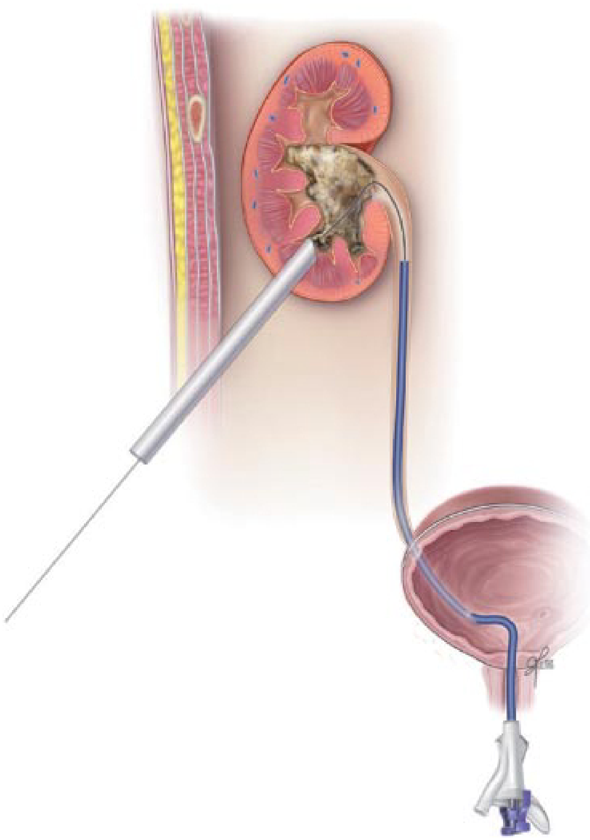

Figure 18.6 Positioning of the nephroscopic sheath (reproduced courtesy of the Cleveland Clinic Center for Medical Art & Photography © 2010. All rights reserved).

Figure 18.7 Nephrolithripsy (reproduced courtesy of the Cleveland Clinic Center for Medical Art & Photography © 2010. All rights reserved).

numbers of subjects. Overall stone-free rates, 63.6–100%, are comparable to series using a purely antegrade technique. Remarkably, very few cases requiring multiple access tracts have been described despite a complex patient population with a large proportion having partial or complete staghorn stones.

Perhaps owing to the limited number of access tracts and reasonable operative times of 70–186 min, complication rates and specifically transfusion rates have been low, with most small series reporting no or one transfusions, and the largest series of 127 patients reporting four cases of transfusion (notably though three of these patients required angioembolization) [5]. Though some reports mention benefits of decreased fluoroscopy time with these techniques, little detail or comparative analysis exists as yet to support this claim.

Despite the fact that the retrograde techniques likely have advantages over an exclusively antegrade approach in certain situations, no prospective or even retrospective comparisons exist to better define its role. Nevertheless, endoscopic technology is continuously evolving and it can be predicted that the role of retrograde assistance and treatment may further expand.

Table 18.3 Case series using ureteroscopy for combined antegrade and retrograde approach to percutaneous nephrolithotomy.

Study	No. of cases	Operative time (min)	Fluoroscopy time	Complications	Stone-free rate after primary treatment (%)	Estimated blood loss (mL)	Miscellaneous
Grasso *et al.* 1995 [10]	7 (3 patients with stones in caliceal diverticula)	N/A (<30 min for access in all cases)	N/A	none	N/A	N/A	For cases with caliceal diverticula, the stenotic infundibulum was dilated with a ureteroscopically introduced balloon to 12F
Kidd and Conlin 2003 [18]	3	N/A	N/A	None	100	N/A	Used selectively for obese patients; patients with hypermobile, ptotic kidney; and patients with complete staghorn stone
Landman *et al.* 2003 [19]	9 total (6 complete staghorn 3 partial staghorn)	186	N/A	4 (atelectasis, ipsilateral leg paresthesia, pulled intercostal muscle, 4-cm perirenal hematoma)	78	290	All patients had one lower pole tract No transfusions
Marguet *et al.* 2005 [13]	7 complex or staghorn stones	142	N/A	None	71.4 (3 and 2 mm residual stones)	79	Single session: ureteroscopy performed in prone position followed by standard prone PCNL. All patients had one tract
Khan *et al.* 2006 [4]	11 for stones (1 case for endopyelotomy and percutaneous nephropexy)	N/A	N/A	Transfusion	63.6 (twosecondary procedures)	N/A	Technique used routinely (not selectively for complex stones or in cases of prior access failure) All patients had one lower pole tract At end of procedure 4 patients with 10F Cope Loop nephrostomy, remainder tubeless All patients had JJ stent placed
Scoffone *et al.* 2008 [5]	127	70, including positioning	N/A	38.6% overall Transfusion: 4 patients Angioembolization for arteriovenous fistula: 3 patients JJ stenting for urinary fistula: 5 patients	81.9	N/A	All cases performed in Galdakao-modified supine Valdivia (GMSV) position Technique used routinely (not selectively for complex stones or in cases of prior access failure) 98.4% of cases with single access tract, majority lower pole access At end of procedure all pts. left with nephrostomy tube 59.9% left with double-J stent

Conclusions

The retrograde technique for percutaneous surgery can provide several advantages over an exclusively antegrade approach, especially in cases in which percutaneous access is difficult. Issues of cost and equipment availability, as well as an undefined degree of benefit, limit our ability to recommend a retrograde approach routinely for all percutaneous cases.

CHAPTER 19

Percutaneous Renal Surgery Selection of Access: Robotic

Michelle Jo Semins, Dan Stoianovici & Brian R. Matlaga

The James Buchanan Brady Urological Institute, The Johns Hopkins University School of Medicine, Baltimore, MA, USA

Introduction

Since the latter part of the 20th century, robotic technology has been applied to a number of industrial and manufacturing processes. Due in great part to potential advantages of motion finesse associated with robotic manipulation, recent years have witnessed an increased interest in the introduction of robotics to the healthcare system. Robots were first introduced to the surgical field in the 1980s, and at that time were focused primarily on neurosurgical and orthopedic applications [1]. As interest in robotics expanded into other medical specialties, urologic applications were soon identified. Since that time, robotics has rapidly assumed an integral role in the urologic armamentarium.

The first reported urologic application of robotic technology was described by Davies *et al*. in 1989, who designed a robot (PROBOT) to perform transurethral resection of the prostate [2–4]. Since that time, a number of targeted research projects have been undertaken to identify and develop applications for robotics within the urologic specialty. In many cases, robotic-assisted surgical approaches have become commonly accepted; robotic-assisted laparoscopic radical prostatectomy may be the best example of this.

The suitability of robotics for urologic surgical applications derives from the properties inherent to robotic technology; namely that these devices are versatile, mechanically capable, and programmable. Tasks that are particularly suited to robotic technology are those that require accuracy, reproducibility, fine motor movements, as well as motion that is difficult to perform by hand due to constrained access, such as for laparoscopy, and ergonomic limitations, such as for magnetic resonance imaging (MRI)-guided interventions. To that end, robotic technology can improve on conventional techniques in, for example, securing percutaneous access to the renal collecting system. In this chapter we will review the genesis and present applications of robotic systems designed to facilitate percutaneous renal access.

Goals of robotic percutaneous renal access

Urology has been one of the surgical disciplines at the forefront of the application of robotic technology, and the kidney is rapidly becoming a target organ for this technology. Robotic-assisted laparoscopic renal surgery, although only recently described, is becoming a standard surgical approach for renal malignancy and reconstruction. Image-guided percutaneous surgery is likely to be the next generation of renal surgery to benefit from robotic technology [5]. Percutaneous renal surgery encompasses a wide diversity of procedures: nephrostomy tube placement, percutaneous nephrolithotomy (PCNL), percutaneous treatment of transitional cell carcinoma, renal biopsy, radiofrequency ablation of renal tumors, and percutaneous renal tumor cryoablation. These many procedures are all potential clinical applications for a robot designed to gain renal access percutaneously.

There are a number of practical advantages to robotic assistance for percutaneous renal therapies. For the urologist, one of the most significant challenges of a percutaneous procedure is applying the three-dimensional (3D) renal anatomy to a two-dimensional

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

image representation. In many cases, this anatomic transposition may be confusing. Reliably and safely attaining an optimal point of renal access can require extensive training and experience. Certain clinical situations, such as entry into a nondilated renal collecting system, can be challenging, even for the experienced clinician. An additional complexity for the urologist, which is not encountered in the orthopedic and neurosurgical fields, is the mobility of the kidney within the retroperitoneum, including its continuous movement with respirations. At many institutions, urologists lack the requisite experience in placing percutaneous access, and such procedures are performed by the interventional radiologist. A lack of participation by the urologist in obtaining percutaneous access for PCNL, for example, may result in the patient undergoing more than one procedure if the access and nephrolithotomy portions of the procedure are performed at times and locations remote from one another. The urologist may also have insights into the manner in which stone removal should be performed, and a lack of such input may result in suboptimal access location. Additionally, there are certain complex clinical scenarios where multiple access sites may be necessary, thus requiring further procedures.

Unlike humans, robots are digital devices that are controlled in 3D space. With proper image registration and navigation algorithms, these can be used to address many of the challenges associated with renal access: improved spatial accuracy, programmable, mechanical, and flexible capabilities, and once designed they can be reproducibly used by a surgical novice. With novel technology that allows constant impedance measurements and rotating needle drivers, many of the abovementioned challenges, such as renal mobility, could possibly be overcome.

The ultimate goals in applying robotic technology to percutaneous access are to increase the ease and decrease the technical challenges of this task, while improving accuracy, efficiency, and reproducibility. Robotic technology holds the potential to provide greater precision than the human hand can, with improved puncture accuracy. Robotic assistance for percutaneous access may ultimately improve surgical performance, and decrease complication rates and operative times [6].

Development and evolution of robotic percutaneous renal access systems

Robotic percutaneous renal access systems were first proposed less than two decades ago by Potamianos *et al*., who performed pioneering work in the creation of a passive robot to facilitate needle placement for percutaneous surgery [7–9]. The system was mounted on an operating room table, required fluoroscopic imaging to guide placement, and had five degrees of freedom (DOF). System performance experiments reported at that time described a 1.5-mm targeting accuracy.

In 1996 our urology engineering program, URobotics, was initiated at Johns Hopkins Medicine [10]. This program is dedicated to the development of new technology and gathers both clinical and technical personnel working in close communication to achieve the goal of robotic image-guided surgery. Many of the robotic systems that have been developed over the last 15 years were developed through this program; these systems will be discussed below.

Modified LARS

A prototype system using a modified Laparoscopic Assistant Robotic System (LARS) was introduced in 1997 by Cadeddu *et al*. [9]. LARS was a modified laparoscopic assistant active robotic system which maintained seven DOF. Each robotic joint was moved by an electric motor, so the access procedure was totally automated. Biplanar fluoroscopic imaging was used to guide the access procedure. The authors described that *in vitro* accuracy was 0.43 mm, and *ex vivo* success with the first attempt was 83%. The authors noted that problems arose with tissue and needle deflection. No comparison to nonrobotic human placement was done with this device, but rather this was a proof-of-concept experiment. This study, despite its limitations, demonstrated that robotic percutaneous access was feasible, although the need for multiple improvements and modifications, such as advanced software, increased DOF, and improved needle design and feedback mechanisms, were identified.

PAKY

The next generation of robotic systems that was developed for renal indications was termed PAKY (which stood for percutaneous access to the kidney), and also is a product of the URobotics program at Johns Hopkins. PAKY consists of a passive mechanical arm with active translational motion providing needle insertion in a compact and radiolucent module. The device is mounted on an operating room table and can be fitted with a standard trocar needle. An active translational mechanism is used for needle advancement, and fluoroscopy is used to align and monitor needle placement. *In vitro* experiments using PAKY were carried out in 1998 with porcine kidneys and *in vivo* studies were completed in nine human patients [11]. Accuracy was 100% in both *in vitro* and *in vivo* attempts. The mean targeted calyx was 14.7 mm in diameter, and the mean time required to gain access was 8.2 min. No complications occurred in any of the trials. These *in vivo* studies demonstrated

the robotic system to be steady, safe, and effective, thus serving as a springboard and providing the groundwork for further development of a complete robotic system.

PAKY-RCM

In 2002 the second-generation PAKY robot, PAKY-RCM (percutaneous access to the kidney with the remote center of motion device), was also introduced by the URobotics program. This is a robot with three active DOF that can remotely align the needle along a selected trajectory pathway under fluoroscopic guidance, minimizing radiation to the surgeon's hands. PAKY is the needle driver and the RCM device is an active robotic arm attached to PAKY that allows the tip of the needle to pivot about a fixed point on the skin. There is a joystick control located on the control box used to advance the needle. Clinical comparison was done using PAKY-RCM versus manual needle placement [12]. There were 23 patients per group and variables measured were number of access attempts, time to successful access, estimated blood loss, and complications. In the robotic group, 87% (20 of 23) of attempts were successful in gaining access. Three patients were converted to manual techniques for various reasons including mechanical failure, and these were successful but took longer than 30 min, illustrating the complexity of the access. All manual access attempts were successful. Only single access was needed for all patients, and no major complications occurred in either group. Time to access was not significantly different between the groups ($P = .06$), with a mean of 10.4 min required for robotic access versus 15.1 min needed for manual access. These investigators again demonstrated the robotic access to be both feasible and safe, with acceptable success rates.

Electrical impedance needle sensor

Entry into the renal collecting system is the requisite endpoint of percutaneous renal access. However, in many cases the urologist has little objective data to confirm this outcome; radiographic imaging can be uncertain and aspiration of urine can be unreliable. To address this clinical problem, the URobotics program designed a "Smart Needle" system, which consists of an access needle fitted with a sensor on the exposed stylet tip that continuously measures electrical impedance (Figure 19.1) [13]. When the collecting system is entered, resistivity drops precipitously. This system was invented to provide objective feedback to the surgeon that access into the renal collecting system has been successfully gained; malpositioning of the needle should be reduced with this device. A series of experiments in which image-guided access to porcine kidneys was performed

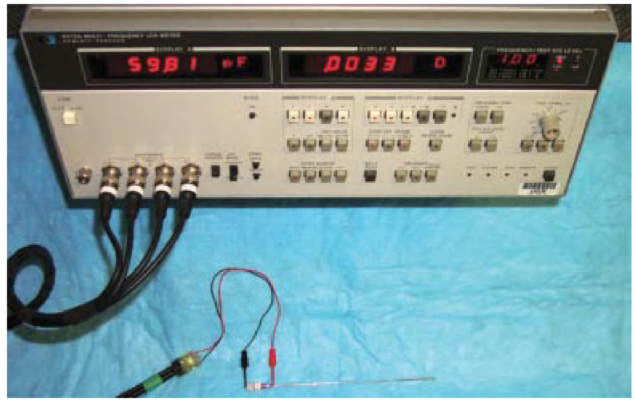

Figure 19.1 Electrical impedance system for the "Smart Needle."

revealed a significant reduction in resistivity when the needle entered the collecting system in 11 of 16 attempts. The promise of the Smart Needle system rests in its ability to optimize renal access, potentially reducing needle-related complications which may occur during this procedure. This needle, which can provide objective feedback to the surgeon gaining access, may reduce the number of access attempts, increase puncture accuracy, and decrease procedure duration. The Smart Needle can be used in combination with any of the previously described robotic systems. It should be noted that the Smart Needle was evaluated only in dilated collecting systems and it is unclear if impedance will drop so precipitously in a nondistended system. In addition, urine with altered chemical make-up, such as grossly bloody or purulent urine, may not demonstrate such an objective reduction in resistivity. Further studies are required to better define these potential limitations.

AcuBot robot

Needle-based therapies such as thermal ablation are increasingly being utilized for the treatment of renal tumors. Due to the image-guided nature of these procedures, there is interest in the design of computer-assisted navigational systems to increase treatment accuracy. AcuBot is a novel, completely automated, robotic system with six DOF capable of needle placement based on imaging data (Figure 19.2). It has the advantage of changing skin locations for entry and has force sensors. Studies have been conducted in phantom models with computed tomography (CT)-guided imaging to assess and compare accuracy between robotic and manual placement by experienced surgeons and radiologists [14]. Accuracy was 1.2 mm for AcuBot needle placement versus 5.8 mm in manual placement ($P < .0001$). The mean time from target acquisition to needle placement was 37 s for the AcuBot and 108 s for the surgeon

Figure 19.2 Clinical demonstration of Acubot robot.

(*P* = .001). This robotic system has the potential to increase both accuracy and operative time, thus decreasing complications and improving clinical outcome. Further studies in animals and clinical experiments are needed to better characterize this promising technology.

Revolving needle driver

Most image-guided robots position and orient a needle guide so that the needle is manually placed through the guide [15]. There are advantages in manually inserting the needle through a guide, such as keeping the physician in direct control of the needle, instrument simplicity, and perhaps facilitating regulatory approvals for clinical trials and use. However, this compromise also mediates the full potential benefits of robotic image guidance [16, 17]. The Johns Hopkins URobotics group has recently developed a tow-DOF needle driver that, in addition to automated insertion, can spin the needle and perform a set of experiments to assess the influence of needle spinning on the accuracy of needle insertion (see Video 19.1) [18]. Figure 19.3 shows the revolving needle driver device supported by the AcuBot robot. Experiments revealed that spinning is useful for improved targeting and could reduce errors by as much as 70%.

Telerobotics and telementoring

Telemedicine has emerged as a promising new field, and provides the ability to disseminate surgical knowledge, particularly complex techniques, to novice surgeons. Both AESOP (robot for remote manipulation of endoscopic camera) and PAKY (percutaneous access of the kidney) have been used to study the utility and feasibility of telesurgery and international mentoring [19, 20].

Figure 19.3 Acubot robot with revolving needle driver.

Among the procedures completed were renal biopsy and percutaneous access to perform nephrolithotripsy or place a nephrostomy tube, which was successfully achieved with PAKY [21].

Telesurgery has been the subject of a randomized control trial, which compared human versus robotic and telerobotic access to the kidney. Using a validated kidney model, the authors found that in over 304 access procedures, humans were faster than the robot (35 s versus 57 s). The robot, however, was more accurate with 88% success of access gained on the first attempt versus 79% success by humans (*P* = .046) [22].

The future

Although much of robotic percutaneous access remains investigational, several systems have been tested and applied to clinical situations with human patients. Several of these systems, as described above, have demonstrated great promise in improving safety, accuracy, and clinical outcomes, while decreasing operative times and complication rates. If these goals are achieved, robotic systems have the potential to be both cost-effective as well as medically desirable. Importantly, in the present medical climate, the cost-effectiveness of these systems must be considered, an area of research that remains to be done. However, as time passes and technology continues to be refined, it is anticipated that

robots will play ever increasing roles in precise and accurate techniques such as those required for percutaneous access.

CHAPTER 20
Dilation of the Nephrostomy Tract

Petar Erdeljan & Hassan Razvi

Division of Urology, Department of Surgery, Schulich School of Medicine & Dentistry, The University of Western Ontario, London, Ontario, Canada
St Joseph's Hospital, London, Ontario, Canada

Introduction

Following creation of percutaneous renal access, tract dilation is an essential step in the performance of percutaneous renal surgery. With proper tract dilation, an appropriate size working sheath can then be placed, facilitating the insertion of the endoscopes, working instruments, and nephrostomy tube.

Dilation of the tract can be achieved in several ways. Use of fascial dilators, Amplatz dilators, metal coaxial dilators, high-pressure balloon dilators, and radially expanding single-step nephrostomy dilators is well described. In this chapter, the features of each dilation modality and their application will be reviewed.

Technique

Regardless of the instrumentation used in tract dilation, there are several technical steps common to each modality. Dilation of the nephrostomy tract follows percutaneous needle puncture into the calyx of interest. The correct placement of the needle is mandatory, as the path of the puncture needle determines which structures are punctured and subsequently dilated. Dilation is always performed over a guidewire. Ideally this wire should be a 0.035 or 0.038 inch extra- or super-stiff variety to minimize the risk of wire bending or kinking. Whenever possible the guidewire should be advanced into the bladder – the additional length of guidewire within the body reduces the chance of inadvertent wire displacement and tract loss during subsequent manipulations. If this is impossible, enough wire should be coiled within the renal pelvis such that the transition point, where the floppy tip and stiff portions meet, is well within the collecting system [1]. Image guidance is essential during tract dilation. Once the super-stiff wire is placed correctly, a 1.5–2-cm skin incision is made around the wire. The dilating instrument is then advanced over the guidewire.

Instrumentation

Fascial dilator systems

The fascial dilator system set is composed of Teflon cylindrical dilators of progressively larger circumference, ranging from 5F to 30F in size (Figure 20.1). Each dilator is designed to be introduced over a 0.038-inch guidewire. The introduction of each dilator is usually carried out in a rotational or spinning motion, under mandatory fluoroscopic guidance.

This system is particularly useful when faced with the need to dilate a heavily scarred tract, following previous percutaneous surgery or in the presence of a retroperitoneal inflammatory process [2]. The main disadvantage of this system is its reliance on the guidewire stability, with potential risk of guidewire kinking leading to dilation failure. This risk tends to be exaggerated with increased length of tract, such as in obese patients. Additional theoretical concern is the application of excessive manual force during the tract dilation, leading to perforation of the medial wall of the renal pelvis, and renal laceration and bleeding [3].

Amplatz dilator system

The Amplatz dilator system, also known as the malleable dilator system, was developed in 1982 by Kurt

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Amplatz to address some of the previously identified disadvantages of the fascial dilator system (Figure 20.2). The set is composed of tapered-tip polyurethane cylindrical dilators, of progressively increasing circumference, ranging from 8F to 30F. The main advantage of this system is conferred by the use of a tapered 8F angiographic catheter. The use of the angiographic catheter provides additional stiffening and stability to the guidewire, thereby decreasing the risk of guidewire kinking.

The 8F angiographic catheter is inserted over the guidewire under fluoroscopic guidance, as an initial step. All subsequent larger dilators are inserted over the 8F catheter and guidewire, in order of increasing diameter. Advancement of each dilator is best accomplished using an alternating clockwise–counterclockwise rotational motion to minimize the chances of guidewire kinking. The shoulders of each Amplatz dilator must be advanced until entirely within the entry calyx. The working sheath is introduced last, over the largest Amplatz dilator until the leading edge of the sheath overlaps the shoulders of the Amplatz dilator (see Video 20.1).

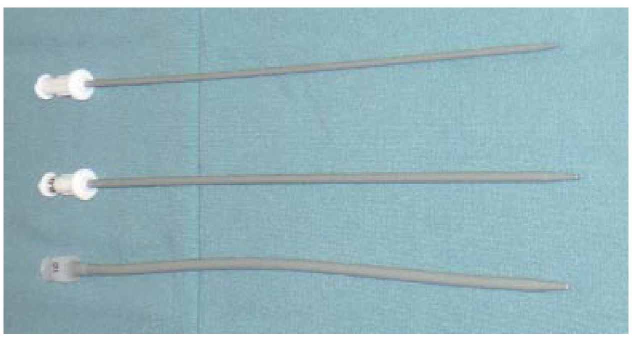

Figure 20.1 Fascial dilators.

An additional advantage of this system is offered by the relative rigidity of the dilators, which in combination with the increased stability and tapered profile, allows greater freedom in dilation of the scarred retroperitoneum. As in the previous system, the main disadvantage is still the theoretical risk of excessive application of force, leading to renal pelvis perforation and renal parenchymal bleeding [2, 3].

Coaxial metal dilator systems

Coaxial metal dilator systems, such as the Alken or Lunderquist instruments (Figure 20. 3), are composed of stainless steel rods which are mounted together in a telescopic fashion. Each dilator is designed to adapt to the lumen of the next successive dilator, starting with an 8F hollow guide rod. The initial hollow guide rod is advanced over a guidewire under fluoroscopy, until its tip is positioned within the renal pelvis. Dilation is achieved with six successive dilators, each increasing in size by 4F, ultimately dilating the tract to either 24F or 26F. A metal guard at the end of each rod represents the endpoint for the insertion of the dilator [4, 5]. The main advantage of this system lies in its rigidity, which provides support for dilating through dense scar tissue. This advantage is offset by increased potential for iatrogenic injury, due to difficulty with controlling the pressure during dilation. Moreover, the necessity for manual stabilization of the central rod during the dilation increases the risk of perforating the renal pelvis.

Modification of the standard Alken metal dilators has been described in an attempt to improve the safety margin [6]. The dilators were modified to become

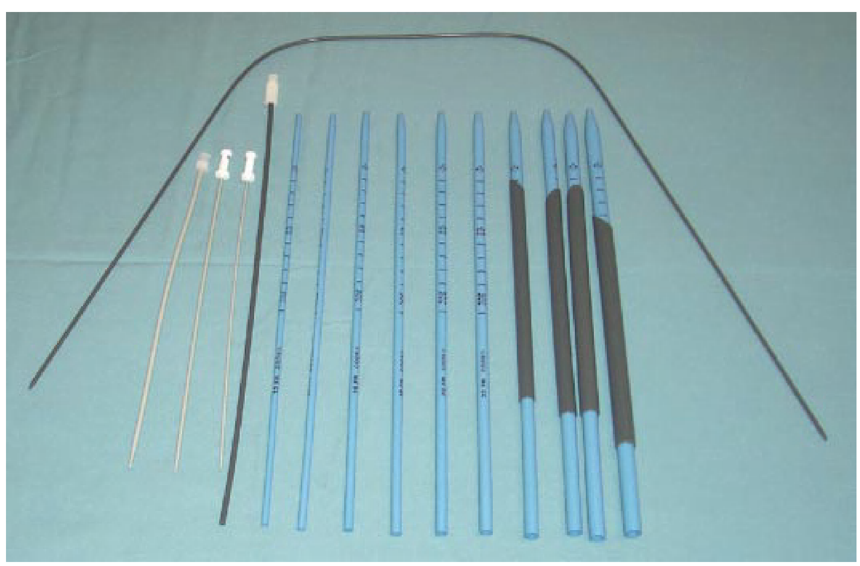

Figure 20.2 Amplatz dilators.

Dilation of the nephrostomy tract – use of metal dilators. In: Smith, A., ed. *Controversies in Endourology.* Philadelphia: WB Saunders, 1995, pp. 42–49, with permission of Elsevier).

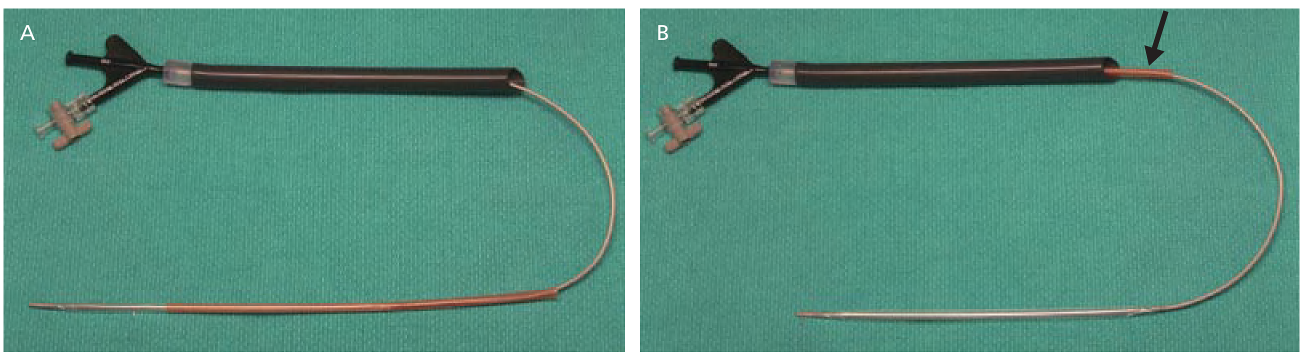

Figure 20.4 Balloon dilator (A) with protective sheath and (B) with protective sheath retained to aid in complete balloon deflation should additional tract(s) be required.

tapered, shorter, nonlocking, thinner, and with centimeter markers on the surface. These modifications have been shown to decrease trauma to the tissues and reduce the chance of renal pelvis perforation from overadvancing the dilators. Additionally, the nonlocking mechanism allows for removal of inner dilators, allowing insertion of a ureteroscope and inspection of the tract and collecting system as the tract is being established [6].

Balloon dilator systems

The use of balloon dilators was pioneered in the field of interventional angiography and has subsequently been adapted for use in other disciplines. The application of balloon dilation to percutaneous renal surgery has been a major advancement.

Percutaneous nephrostomy tract balloon dilators are intended for creation of tracts in a rapid, single step, eliminating the need for serial dilation. They are designed to be introduced into the collecting system over a guidewire and tract dilation is carried out under fluoroscopic guidance. The balloon dilator set consists of an expandable balloon, 30F working sheath that is back-loaded before the deflated balloon is placed over the wire, and syringe inflator (Figure 20.4A). Pressures of up to 20 atm can be easily achieved with this system, although in general, much lower pressures are usually sufficient for tract creation. Balloon inflation allows for full expansion of the balloon, which is followed by insertion of a working sheath over the balloon, in a rotational manner.

The main advantage of the balloon dilation technology lies in the fact that the tract is created using lateral, rather than angular, shearing forces. In theory, lateral forces are less traumatic and reduce the chance of large vessel injury and resultant hemorrhage. An additional advantage is the elimination of serial dilation, which saves operating room time [7]. The dilation is also more controlled, as the balloon can easily be stabilized during

the inflation. In earlier experience, the use of balloon dilators was found to result in a lower rate of blood transfusions in comparison to Amplatz and fascial dilators [8, 9]. Contemporary series comparing the Amplatz and balloon dilation systems have suggested the differences in complications may not be significant [10, 11].

The main disadvantage of balloon dilators are their relative higher cost compared to the other systems. The balloons are designed for single use only, further adding to their expense. In a case where more than one tract is required, the same balloon can be used again. To do this requires complete deflation of the balloon of all contrast such that there are no wrinkles in the balloon profile. This can be achieved by using the protective sheath that covers the balloon when the package is first opened (Figure 20.4A). Rather than removing this protective sheath, we have found it easier simply to slide it away from the balloon segment, but keeping it on the catheter. The protective sheath can then be pulled back over the balloon portion should the surgeon need to use the balloon again in the same case to dilate an additional tract(s) (Figure 20.4B).

Other concerns with the balloon catheters include an inability on occasion to dilate through dense scar tissue and the risk of balloon rupture causing barotrauma.

In most situations, the balloon dilator is advanced until the proximal radio-opaque marker is positioned within the entry calyx (see Video 20.2). Correct placement of the balloon dilator is essential to provide a useful tract and to avoid significant bleeding. To aid in proper placement, retrograde contrast injection via the previously placed ureteral catheter will delineate the collecting system. The balloon should not be inflated within the infundibulum to avoid potentially significant hemorrhage (see Video 20.2). It should also be mentioned that with most of the balloon dilators on the market, a short segment of balloon extends beyond the proximal radio-opaque marker. The features of the balloon being used must, therefore, be understood so this can be compensated for when placing the balloon into the entry calyx, to avoid over dilation.

Balloon inflation is performed using radiographic contrast instilled within the injector syringe. The balloon should be inflated until no "waisting" or focal narrowing is evident (Figure 20.5). The pressure required to dilate the tract is generally under $15\,cmH_2O$. The balloon dilator should be manually stabilized during this procedure in order to avoid inadvertent displacement. Next, a 30F working sheath is advanced over the inflated balloon. This maneuver is facilitated by slowly advancing the sheath while rotating it over the balloon, under fluoroscopic guidance (see Video 20.2). Care should be taken while the sheath is being advanced that the balloon does not advance into the renal pelvis. The

Figure 20.6 Radially expanding single-step nephrostomy (RESN) dilator. (A) 8F woven sleeve with an inner stylet, a 30F tapered fascial dilator, and an Amplatz-like working sheath. (B) Inner stylet placed in the woven sheath and the Amplatz-like sheath tightly fitted and fixed in position relative to the tapered fascial dilator (reprinted from Goharderakhshan *et al*. [12], with permission of Elsevier).

balloon dilator is removed and the super-stiff wire secured to the drapes. At this point nephroscopic instrumentation can be introduced and stone removal undertaken.

Radially expanding single-step dilator system

A relatively new technique of tract dilation involves the use of a radially expanding single-step nephrostomy dilator (RESN) [12]. This device is made of four components: an 8F woven sleeve with an inner stylet, a 30F tapered fascial dilator, and a working sheath (Figure 20.6). The 8F woven sleeve with a rigid stylet is introduced over the guidewire under fluoroscopic guidance. The stylet is removed following the insertion, leaving the woven sleeve in the collecting system. The tapered fascial dilator with a back-loaded working sheath is inserted through the sleeve in order to dilate the tract. The sleeve must be locked in place with the nondominant hand during the dilation, in order to counterbalance the forward force of the dilator. Following the insertion of the dilator, the woven sleeve undergoes radial expansion, accommodating the insertion of the working sheath. The working sheath and the fascial dilator have to be secured in position, relative to each other, in order to eliminate inadvertent advancement of the sheath over the tip of the dilator.

The main advantage of the RESN system, like that of the balloon dilator, is in the use of lateral forces which minimize tissue trauma. In addition, the RESN system concentrates the radial forces at the tip of the dilator, thereby offering an advantage during the dilation of a heavily scarred retroperitoneum.

The main disadvantage of this system is the use of significant manual force and manual counterbalancing during the dilation, which have a potential for inducing significant renal trauma. The use of this system was initially described in a small series [12]. Its comparative efficacy and safety relative to the balloon dilator remains to be determined.

Special considerations

Obesity

A number of studies have demonstrated that percutaneous nephrolithotripsy (PCNL) can be performed effectively and safely in obese patients [13–15]. Accomplishing tract dilation, however, can be challenging due to the long tract length required, risking guidewire buckling or kinking, and an inability to reach the collecting system with the dilation instrument. This latter problem may occur with the balloon dilators. The balloon component of most dilating devices on the market is 15 cm long. In the morbidly obese patient, the balloon may be buried beneath the skin in order to reach the collecting system, making it difficult to advance the working sheath. The use of Amplatz dilators may be chosen in this scenario. With a length of 30 cm, each Amplatz dilator should be able to reach the collecting system regardless of patient size. An extra long working sheath may be required however, and should be kept on hand for such contingencies. Should the working sheath need to be buried beneath the skin, we choose to place a large silk suture through the sheath so that the sheath can easily be retrieved at the completion of the case.

Alternatively, the standard Amplatz dilator set can be augmented with the addition of a modified 10 mL syringe barrel. This modification prevents migration of the working sheath below the skin and effectively extends the length of the working sheath [16].

Pediatric patients

Continuous miniaturization of endoscopic equipment and refinement in the surgical technique has allowed percutaneous stone surgery in children. Several studies have reported on the safety and efficacy of PCNL in the pediatric population [17–21]. Tract dilation in children can be carried out with serial dilation or balloon dilation. Use of a 24F balloon dilator minimizes potential parenchymal trauma and bleeding. The technique is identical to that previously described in the adult population. Alternatively, the mini-perc technique can be used. The mini-perc access system uses an 11F × 10 cm peel-away vascular access sheath with an exposed trocar length of 1 cm. The sheath is inserted into the collecting system over an access wire and does not need sequential or balloon tract dilation. The mini-perc technique reduces the size of the percutaneous tract significantly and yet can still be effective for clearing stones [22]. It is also associated with decreased blood loss, increased maneuverability, and shorter hospital stay [23], but requires mandatory use of pediatric instruments and a greater degree of stone fragmentation prior to extraction.

Retroperitoneal scarring

Retroperitoneal fibrosis resulting from previous surgery or retroperitoneal inflammation can present a challenge during nephrostomy tract dilation. Balloon dilators used in this situation have been associated with failure rates of 17–50% [24, 25]. Balloon failure cases can be salvaged in most situations with the use of Amplatz or metal dilators.

Alternatively, when dense perinephric scarring is encountered, the use of a facial incising needle can also be used to aid tract dilation. The needle (Figure 20.7) is advanced coaxially over a previously inserted guidewire to facilitate subsequent tract dilation. The needle is rotated as it is advanced, breaking through dense fibrosis. Care must be taken not to inadvertently lacerate the subcostal or intercostal neurovascular bundle on the inferior rib margin [26]. Among thin patients, care must be taken not to advance the needle too deeply, so as to avoid reaching and lacerating the renal parenchyma.

A recent report has described the use of a cutting balloon for cases of heavy retroperitoneal scarring [27]. Although described as safe and successful in this case report, its safety in a wider context remains to be determined.

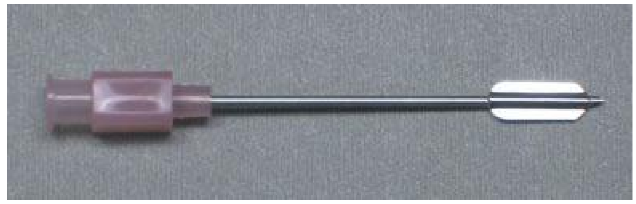

Figure 20.7 Fascial incising needle.

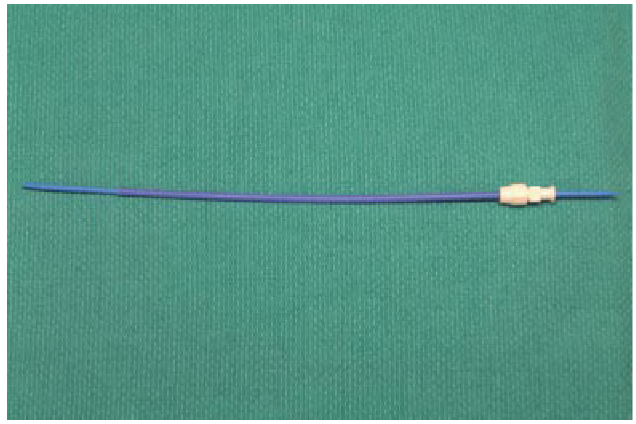

Figure 20.8 8–10F coaxial dilator.

Impacted stone in entry calyx

Renal stones tightly impacted within the intended entry calyx present a challenge for percutaneous surgery. The access can be aided by injection of contrast, relying on the generated pressure to create space around the stone [26], the use of hydrophilic wire(s) or angled-tip catheters, such as a Kumpe catheter to navigate around the stone. The main challenge in dilating the tract is to ensure the dilator can obtain enough purchase within the calyx to allow insertion of the working sheath. In this scenario, initial dilation with an 8–10F coaxial catheter (Figure 20.8) may be attempted. This maneuver will often create enough space to permit a successful reinsertion of the balloon catheter.

Potential complications

Hemorrhage

Acute hemorrhage can originate from four sources: intercostal vessels, renal parenchymal vasculature, or branches of the renal vein or renal artery adjacent to the pelvicalyceal system. The reported incidence of serious arterial injuries ranges from 0.9% to 3% after percutaneous procedures (Table 20.1) [6, 7, 9, 11, 25, 28–31]. The most clinically significant bleeding related to percutaneous tract dilation is due to over-advancement of the dilating instrument, resulting in splitting of the infundibulum. This occurrence can be avoided by

understanding the anatomy of the entry calyx and infundibulum with retrograde contrast injection. Regardless of the dilating system used, the intention should then be to place the widest part of the dilator into the entry calyx, but not into the infundibulum.

Renal pelvis perforation

The most common cause of renal pelvis perforation is the aggressive use of serial dilators. The perforation is usually medial, following an over-advancement of the dilator. Renal pelvis perforation can also occur due to initial transgression of the puncture needle and inappropriate guidewire positioning. Acute angulation, often associated with lower renal pole entry, and guidewire kinking can also contribute to renal pelvis perforation. Initial advancement of the guidewire down the ureter and into the bladder facilitates dilation and greatly reduces the risk of this complication.

The perforation is usually recognized intraoperatively by contrast extravasation on fluoroscopy. Once recognized, it requires termination of the procedure and placement of a ureteral stent and a nephrostomy tube.

Conclusions

Acute dilation of the percutaneous nephrostomy tract is a safe and efficient technique that permits percutaneous renal surgery. A variety of dilating techniques and instruments can be used, each with specific advantages and risks. The dilation should always be carried out over a guidewire and under radiologic imaging. The choice of equipment will depend on patient profile, surgeon preference and expertise, local instrument availability, and costs.

CHAPTER 21
Rigid and Flexible Nephroscopy

Mantu Gupta & Hiroshi Katsumi
Columbia University, Department of Urology, New York, NY, USA

Introduction

The first reported nephroscopy was performed in 1941 when a rigid cystoscope was placed into the kidney through a drain tract to remove stones after open kidney surgery [1]. Subsequent to this, the first percutaneous renal access was obtained in 1955 for hydronephrosis. The percutaneous route for accessing the kidney has grown in popularity, starting with the increasing use of percutaneous nephrolithotomy (PCNL) in the 1980s [2]. PCNL is now the gold standard for the removal of staghorn renal calculi due to its minimally invasive nature and high stone-free rates [3]. Rigid nephroscopes are most commonly used to clear stones from the collecting system during PCNL; however, there are times when, due to anatomic constraints, this instrument cannot perform all of the functions needed to render a patient stone free due. Also, with advances in instrumentation, use of percutaneous access has expanded to treating renal diseases such as symptomatic renal cysts, stenotic infundibula, excluded calyces, and upper tract transitional cell carcinoma.

This chapter will discuss recent advances in rigid nephroscopy, flexible nephroscopy through percutaneous access, and instruments and techniques that can maximize efficiency and minimize morbidity during various percutaneous renal procedures.

Indications for nephroscopy

Diagnostic indications

With advances in imaging technology boasting diagnostic accuracy of 76–98% for upper tract urothelial carcinoma, and better flexible ureteroscopic equipment, such as digital imaging scopes and ureteral access sheaths, nephroscopy as a purely diagnostic procedure is not routinely performed [4–6]. Occasionally, percutaneous access is the only option for access to the pelvicalyceal system, e.g. extremely difficult retrograde access after cystectomy and urinary diversion.

Therapeutic indications

With the combination of rigid and flexible nephroscopy techniques, percutaneous nephroscopy can be used to treat the following:
• Stone disease: treatment of complex calculi/staghorn calculi;
• Upper tract transitional cell carcinoma (TCC): ablation of tumors with lasers or resection with a cautery system;
• Ureteropelvic junction (UPJ) obstruction: antegrade endopyelotomy and/or endopyeloplasty with a balloon cutting device, holmium:YAG laser incision, hook knife, Sachse urethrotome, or endoscopic shears [7];
• Obstructed calyces, infundibular stenosis, and calyceal diverticula: access obtained in a "direct" manner in which the percutaneous access is directed at the obstructed area or an "indirect" approach where the obstructed area is accessed via another puncture site.

Indications for flexible nephroscopy

The chief indication for flexible nephroscopy is access to calyces with stones or tumors that cannot be reached

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

with the rigid nephroscope. Williams *et al*. showed that a combination of flexible and rigid nephroscopy can be successfully used to render patients stone free, even in the face of complex stone disease [8]. Such studies show that urologists must now strive for stone-free status with a single procedure [9]. Although some studies have shown greater cost with increasing stone burden, it is unlikely that insurance companies or patients will permit the cost and morbidity of repeat PCNL procedures in the future as more urologists will have the ability to render patients stone free with one procedure [10]. Even after discharge, the cost of time away from work and to the healthcare system from secondary procedures precludes multiple sessions of extracorporeal shock-wave lithotripsy (ESWL) or repeat PCNL. In addition, the 90-day global period after PCNL surgery in the USA makes secondary procedures unappealing to urologists. However, most urologists performing percutaneous procedures commonly encounter situations where a procedure cannot be completed through a single percutaneous access. The options for dealing with these situations include obtaining another access that is more amenable to reaching the stone, leaving the stone and performing ESWL or ureteroscopy, or performing flexible nephroscopy. Flexible nephroscopy has been growing in popularity recently as surgeons have shown its use can avoid the need for an additional access [8, 11].

Flexible nephroscopy can also be used through a percutaneous access to treat obstructed calyces or a calyceal diverticulum when a rigid nephroscope cannot reach the infundibulum due to its acute angle or tightness (Figure 21.1) [12]. This indirect approach to an obstructed calyx or calyceal diverticulum is becoming more commonly utilized as opposed to a direct approach, wherein the obstructed calyx itself is percutaneously punctured, a tract established, and the stenosis treated directly. The advantage of the indirect approach is that it obviates the need for a separate nephrostomy tract with its attendant morbidity.

Occasionally, a conventional flexible cystoscope can be too large or too cumbersome to be maneuvered into a calyx. In such instances, use of a flexible ureteroscope to access difficult-to-reach calyces increases the chances of rendering a patient stone free. These are generally 7 or 8F and tend to have better deflection than the flexible cystoscope. Problems are encountered with fiberoptic flexible ureteroscopes because of their length and they are not ergonomically suited for use in the kidney; relatively flimsy nature and thus they are not torque stable; and slender profile and tight distal radius of deflection, making them difficult to maneuver in hydronephrotic collecting systems. Use of nephroscopy with a ureteroscope should be considered for stone fragments that may have migrated down the ureter during stone fragmentation in the renal pelvis.

Figure 21.1 Stenotic infundibulum.

The need for flexible nephroscopy during PCNL depends largely on the location of the stone and of the access. Most urologists prefer to obtain access below the 12th rib in order to reduce the risk of pleural injury. In those cases, the rigid nephroscope is usually introduced into the lower pole. The renal pelvis can usually be reached with this access, but reaching upper and mid pole calyces without placing substantial torque on the renal parenchyma is difficult, especially in obese patients or in patients with low-lying kidneys due to hindrance from the iliac crest. It can also be challenging to reach other lower pole calyces from this position and almost impossible to evaluate the proximal ureter with a rigid nephroscope (Figure 21.2). Alternatively, if access is into the upper pole, it can also be difficult to reach the lower pole calyces, especially in patients with narrow intercostal spaces or nonmobile (fixed) kidneys.

Preoperative routine

Preoperative planning should include a careful review of imaging, whether an intravenous pyelogram or a computed tomography (CT) scan. Generally, a CT scan will enable the surgeon to better assess the anatomy, stone burden and location, and calyceal structure of the kidney to be accessed. Particular attention should be given to the location of pleura in relation to the kidney, as well as any bowel and organs that could be in the access path; especially in cases of anomalous kidneys (malrotated kidney, horseshoe kidney, ptotic kidneys, pelvic kidneys, cross fused ectopia, etc.) that may force the surgeon to obtain unusual access [13–15]. In

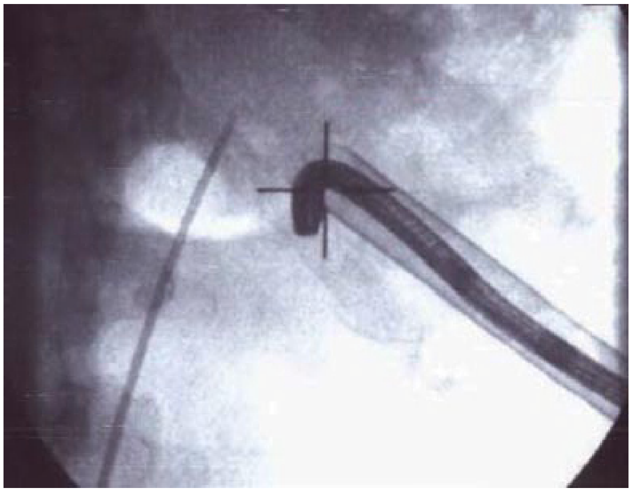

Figure 21.2 Reaching the lower pole calyx with a flexible scope.

Table 21.1 Concordance of preoperative voided urine cultures with intraoperative renal pelvis and stone.

Type of specimen	Positive culture	Matches preoperative voided urine Culture	Matches intraoperative renal pelvis culture
Preoperative voided urine culture (n = 57)	18 (31%)	N/A	–
Intraoperative renal pelvis culture (n = 57)	9 (16%)	5/9 (55%)	N/A
Intraoperative stone culture (n = 57)	10 (17%)	4/10 (40%)	3/10 (30%)

planning the treatment of UPJ obstruction with endopyelotomy, a CT scan of the abdomen in an angiographic phase should be obtained to delineate the presence of a crossing vessel.

Preoperative urine culture should be obtained and be negative whenever possible. However, in cases where a patient may have an infected renal calculi, it may be difficult to achieve complete sterility even with culture-specific preoperative antibiotics. In fact, data from our institution suggest that there is a fair degree of discrepancy between preoperative voided urine culture, intraoperative renal pelvis culture, and intraoperative stone culture [16]. Table 21.1 shows the concordance of the urine cultures obtained in patients who underwent PCNL at our institution.

Other laboratory work-up should include tests for renal function and electrolyte abnormalities. Patients should be instructed to stop all Aspirin products at least 10 days prior to surgery. Patients who are constantly anticoagulated on warfarin need to discontinue this to allow the PT/INR to normalize, and short-acting heparin products given instead. Typing of blood should always be obtained prior to surgery, as well as blood transfusion consent.

Perioperative routine

Generally, percutaneous renal procedures are performed with general anesthesia with the patient in the prone position. Recently, studies have shown that PCNL can be safely performed under regional anesthesia and in other positions such as a lateral decubitus position [17, 18] (see Chapters 8, 10, and 11). Surgeons have performed successful percutaneous procedures using the following patient positions:

Publisher's Note:

- Prone;
- Prone on spreader bars: allows access to genitalia to perform simultaneous retrograde nephroscopy [19];
- Prone–flexed: allows better access to upper pole [20];
- Supine position: allows normal anesthesia access to respiratory tract; allows easy access to lower urinary tract;
- Valdivia–Galdakao position: intermediate dorsal decubitus position with extension of ipsilateral lower limb and flexion of contralateral lower limb [21, 22].

Advances in scope technology

Although flexible scopes afford more maneuverability, there is little disagreement that the quality of the image is better with a rigid nephroscope; especially with the advent of the new rigid Smith digital nephroscope (Figure 21.3) (Gyrus; ACMI, Southborough, MA, USA) [23]. This scope allows access to calyces that are not normally accessible with rigid nephroscopes because it boasts a large working channel with better irrigant flow

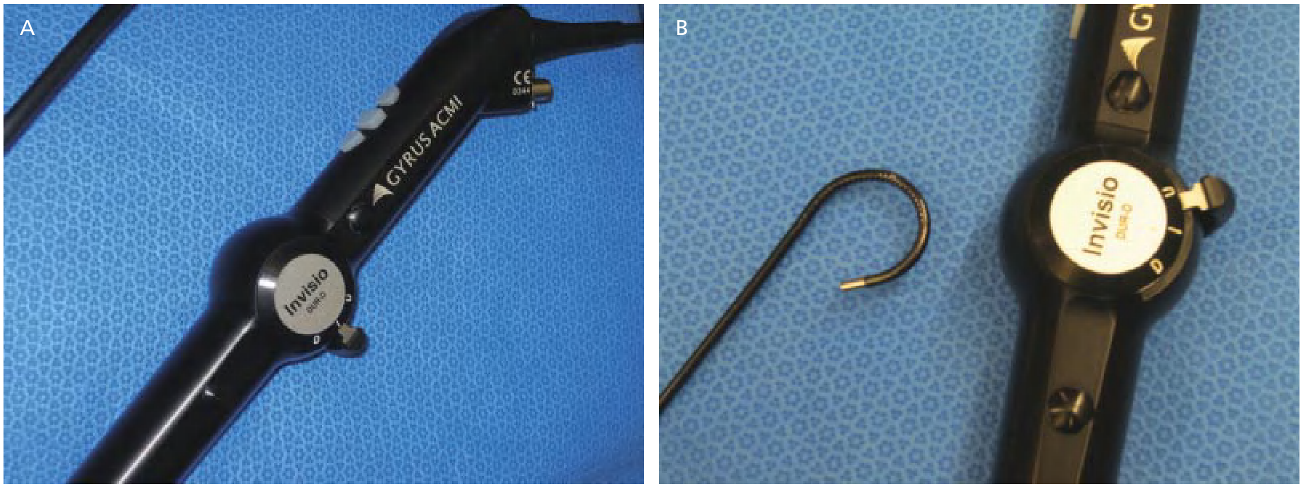

Figure 21.4 Invisio DUR-D digital flexible ureteroscope (Gyrus ACMI, Southborough, MA, USA).

(15F), is longer (18 cm vs 15 cm), lighter (470 g compared to 939 g), and more maneuverable without a bulky camera head. Its digital "chip on a stick" technology allows better contrast, color, and resolution than other scopes, making it easier to identify infundibulae even in the face of severe edema, bleeding, or stenosis. In addition, the dual distal light emitting diode (LED) light sources eliminate the need for a separate light cord and improve image brightness.

There are also new and improved digital flexible cystoscopes that show improved color, contrast, and resolution compared to traditional fiberoptic cystoscopes. Studies comparing digital to fiberoptic cystoscopes have shown that the digital scopes have improved resolution, contrast discrimination, and red color differentiation and are as durable as the older scopes [24, 25]. In addition to optics, the digital cystoscopes also have better deflection in both directions and are more torque stable compared to their fiberoptic counterparts, making navigation easier, especially in very tight or very hydronephrotic collecting systems.

A new advance in the use of flexible ureteroscopes for access to difficult-to-reach calyces and the ureter is the digital distal sensor ureteroscope (DUR-D, ACMI) (Figure 21.4). This scope provides excellent resolution and superior optics compared to traditional fiberoptic ureteroscope. It also deflects further away from the distal tip (270° degrees in either direction), giving it better maneuverability (Figure 21.5). At 8.5F, it will fit into most calyces.

A very useful technique that has been recently described and adopted is placing the flexible ureteroscope through the working channel of the rigid nephroscope so that it can be better directed toward an intended target (Figure 21.6). This is particularly useful with an additional video tower so that images from both the nephroscope and the ureteroscope can be simultaneously viewed. In particular, placing the DUR-D digital

ureteroscope through the large working channel of the new Invisio Smith digital nephroscope provides a fantastic image [23].

Importance of access site

As mentioned earlier, initial percutaneous access to the kidney influences which calyces can be reached. If a patient has a single stone in a mid pole calyx, it makes most sense to access that calyx directly. If there are multiple stones or staghorn calculi, access is often obtained in the upper or lower pole, making mid pole access difficult to reach with a rigid scope. Also, since a rigid scope entering posteriorly faces the anterior calyces, it is more difficult to go from a posterior calyx to another posterior calyx. Some general guidelines for various access sites are given below.

Posterior upper pole access

If posterior upper pole access is obtained, generally the other more anteriorly located upper pole calyces can be reached with the rigid nephroscope even if there is a moderate degree of hydronephrosis. If there is no significant hydronephrosis, or if the access site is close to the infundibulum instead of the peripheral end of the calyx, then it most likely will not be possible to visualize or enter the other upper pole calyces and flexible nephroscopy is necessary. From the upper pole, usually the anterior lower pole calyces can be entered with the rigid nephroscope, but the posterior ones cannot (Figure 21.7). Unless there is significant hydronephrosis, the mid pole calyces cannot be entered at all and flexible nephroscopy will be necessary.

Mid pole access

As previously mentioned, if posterior mid pole access is obtained, usually the rigid scope cannot access anything other than the renal pelvis and ureter. This access should only be chosen if stones are located in a solitary mid pole calyx and/or the renal pelvis or proximal ureter.

Posterior lower pole access

With a posterior lower pole approach, often the other more anteriorly located lower pole calyces can be entered if the access site chosen is more *medial* than usual. To achieve this, instead of rotating the C-arm through the usual 30º toward the surgeon, it is rotated only 20º. This slightly more medial approach, in our experience, does not risk vascular injury and yet provides excellent ability to reach all lower pole calyces. It is particularly useful for partial staghorn calculi that have no upper or mid pole components. From the lower pole, unless there is severe hydronephrosis, the upper and mid pole calyces cannot be reached at all and flexible nephroscopy is necessary to clear them of residual stones (Figure 21.8).

Likewise, the ureter cannot be accessed with rigid scopes or instruments, and flexible scopes are needed. Use of the Accordion™ device (Percsys, Palo Alto, CA, USA), a 15-mm coaxial film-based occlusion device, permits lower pole access for complex stones without

fear of stones migrating down the ureter that will then require flexible ureteroscopy at the end of the procedure (Figure 21.9) [26]. Use of this device can ultimately help save time and cost of percutaneous stone procedures.

Figure 21.8 Reaching upper pole calyces with lower pole access.

Intercostal access

The degree of maneuverability also depends on whether triangulation was used to obtain upper pole access or if an intercostal approach was chosen. Intercostal access will usually allow more maneuverability with less torque on the renal parenchyma, provided that the intercostal space is wide enough. On occasion the space between ribs is very narrow and the sheath is sandwiched so tightly that maneuverability is significantly hampered.

Tips and tricks

Flexible nephroscopy

This section will discuss different techniques that assist with use of the flexible nephroscope and obtaining safe percutaneous access. One tip is to minimize the use of contrast. If contrast extravasates outside the collecting system, fluoroscopic visualization of residual stones is very difficult. In our experience, contrast is used only at the very beginning of the procedure to outline calyceal anatomy and to help guide access, then again at the very end after the nephrostomy tube has been placed.

Often, visualization is adequate with a rigid scope because of high volume irrigation, but once the flexible scope is employed visualization dramatically deteriorates if there is any bleeding at all. This is partly due to the optics, but even more to the reduced irrigation with

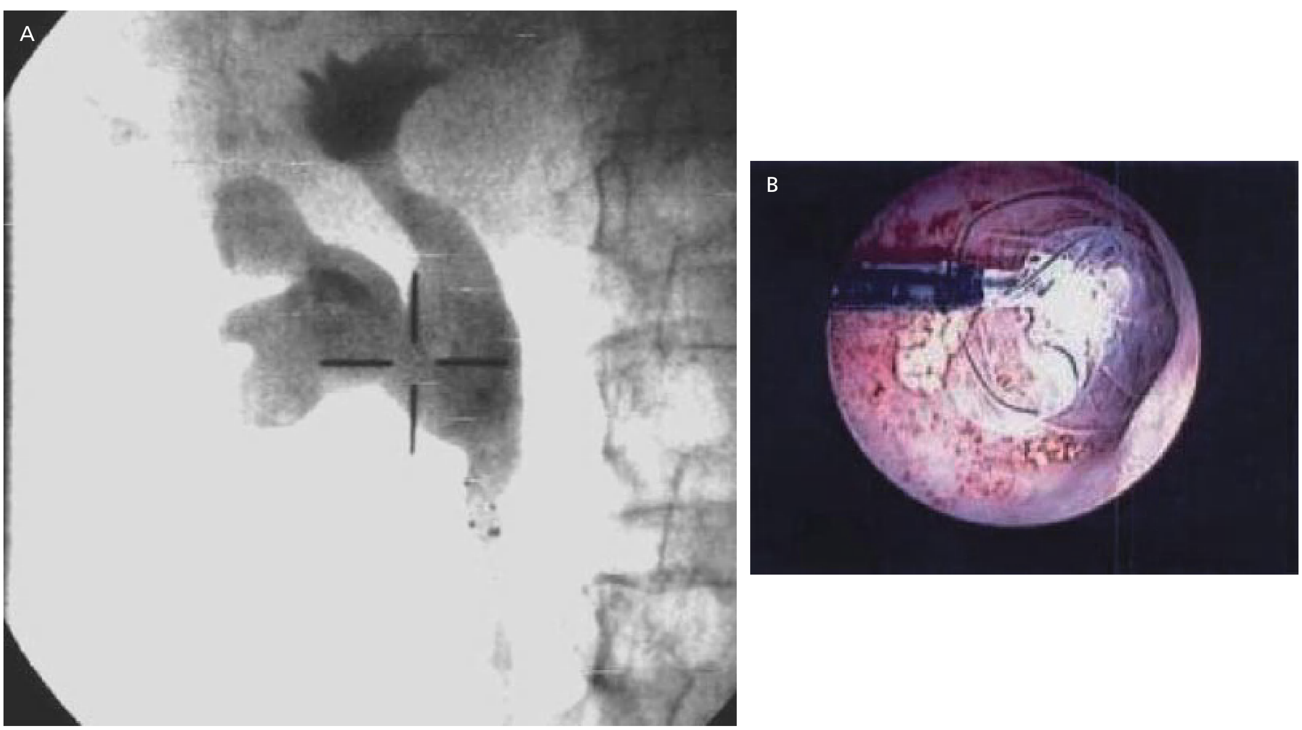

Figure 21.9 Fluoroscopic image of the Accordion™ device (Percsys, Palo Alto, CA, USA) deployed at the ureteropelvic junction. (B) Accordion device preventing antegrade stone migration.

a flexible scope and the inadequate distention of the collecting system. Use of pressure bag irrigation can significantly enhance visualization by clearing the field of blood and by distending the collecting system.

One important technique is the use of fluoroscopy to help guide placement of the flexible nephroscope. If direct visualization is not sufficient to visualize an intended calyx (either because of angulation, a severely hydronephrotic collecting system, or bleeding), brief continuous fluoroscopy can be used to gently maneuver the scope to a stone in a peripheral calyx. This is generally a very safe maneuver because the blunt end of a flexible nephroscope is wide and atraumatic. Also, since the scope is flexible, perforation is unlikely.

If the opening to a calyx can be visualized with a rigid scope, but it is difficult to find with a flexible scope because of bleeding or incomplete distention of the collecting system, a guidewire can be placed into the intended calyx via the rigid scope. The best wire to use for this purpose is a short, heavy-duty J wire (Cook Urological, Spencer, IN, USA). The short J wire with the "J" hooked distal tip is atraumatic and therefore is less likely to perforate the calyx or to be dislodged while transitioning from the rigid scope to a flexible one. The flexible scope is not placed over the wire, which almost always results in the wire becoming dislodged from the calyx; instead, the flexible scope is placed alongside the wire and the wire is followed to the calyx of interest. In this manner, the working port of the flexible scope is free for the placement of instruments. In addition, the calyx can be entered again and again without the wire having to be replaced.

Another tip mentioned earlier is placing a flexible ureteroscope through the rigid nephroscope. This is particularly useful when the infundibulum to the targeted calyx is narrow and will not accommodate a flexible nephroscope. The smaller girth of the flexible ureteroscope means it can enter almost all calyces, but maneuvering these scopes in the collecting system can be challenging because of poor irrigation through their small working channels, their excessive length, their tight radius of curvature, and their lack of torque stability. By visualizing the infundibulum with a rigid scope, the flexible ureteroscope can be guided into the calyx by a second surgeon through the working port of the rigid scope, which the first surgeon holds steady. Once the calyx is entered, the camera can be switched to the flexible scope. Alternatively, two video towers can be employed so that simultaneous views from the rigid and flexible scopes can be obtained.

Stone fragmentation, retrieval, and patient positioning

Once the affected calyx is reached with the flexible nephroscope or ureteroscope, the size of the stone(s) to be removed must be gauged relative to the width of the infundibulum. If it is likely that the stones can be pulled through the infundibulum intact, a basket or grasper can be used. The N-gage basket (Cook Urological) is particularly useful for efficiently grasping a stone (Figure 21.10). The advantage of this device is that it has an open end and can "cup" a stone that is attached to a papilla or is impacted against the wall. In addition, if the stone is too large to pull through the infundibulum, it can be easily released.

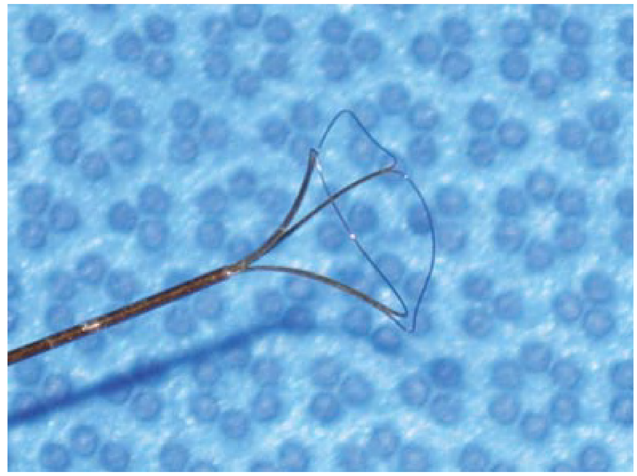

Figure 21.10 N-gage basket (Cook Urological, Spencer, IN, USA).

Baskets are useful for free-floating stones. A basket must be chosen that is sturdy enough to remove the fragments but small enough to allow the scope to deflect. For flexible nephroscopes with their large working channels, 2.4 or 3F nitinol baskets should be used because they are sturdier than smaller profile baskets and can grab larger fragments. For flexible ureteroscopes, 8F or smaller baskets are preferred because they permit better irrigation.

If the stones to be removed are too large, the holmium:YAG laser can generally be used for lithotripsy. It is important to balance the size of the fiber with the deflection of the scope; a larger fiber will make it more difficult to deflect but will disintegrate the stone faster. Most endourologists generally use a 360-μm fiber through the flexible nephroscope, but a 200-μm fiber through a flexible ureteroscope as it easily fits through all flexible ureteroscopes without significantly affecting deflection or irrigation. The settings to be used depend on the effect desired and the nature of the stone. If the intention is to create miniscule particles that will be left behind for spontaneous passage or flushed out of the calyx and then suctioned (uric acid, phosphate, and struvite compositions are most amenable to this), then low power (i.e. 0.5 J) at a faster frequency (i.e. 10–15 Hz) should be used, and the periphery of the stone should

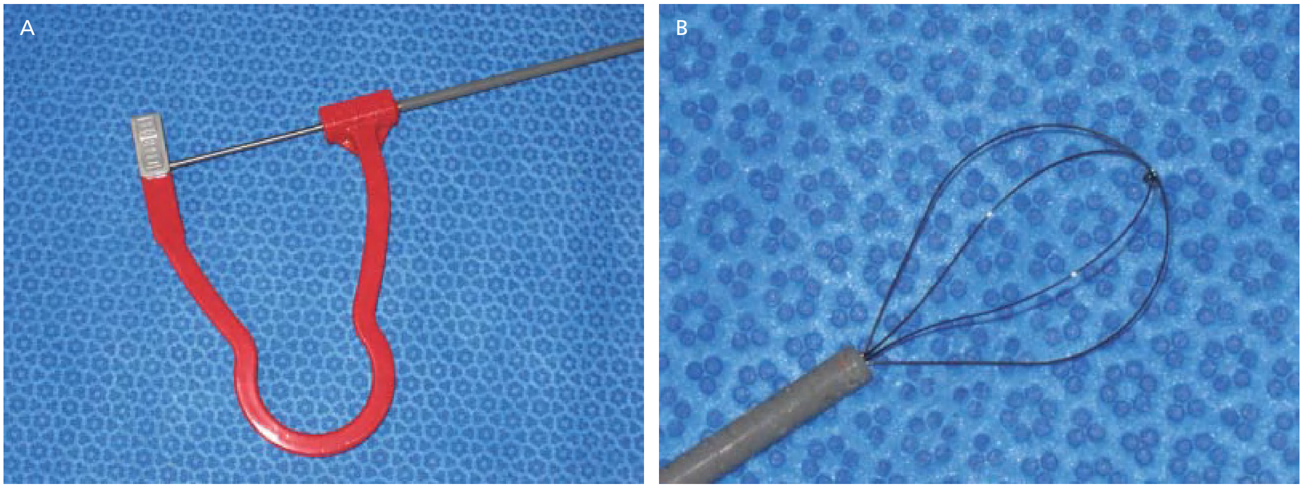

Figure 21.11 Perc-N-Circle device (Cook Urological, Spencer IN, USA).

be ablated gradually until the center is reached. The remaining central piece can be retrieved with a grasper or basket. If the stone is very durile (e.g. a calcium oxalate monohydrate or cystine stone), then it should be carved into a few large pieces using high power (1.0 J) and lower frequency (5–8 Hz). The resultant pieces should be removed in piecemeal fashion.

Tiny fragments that are too small to basket are often broken off by the laser. One technique is to irrigate with a 10-mL syringe through the working channel of the flexible scope to flush out these fragments. If they are small enough, they can even be aspirated with the syringe. The most effective technique also includes changing the position of the patient to maximize the drainage of these fragments. For instance, if the patient is in the prone position and the fragments being flushed are in an anterior calyx, the patient can be rotated to the opposite side so the fragments fall into the renal pelvis. One can also use Trendelenberg and reverse Trendelenberg as necessary to allow stones to enter the renal pelvis. Fragment migration into the ureter is mitigated by using the Accordion device, as mentioned above. From the renal pelvis, the fragments can be easily retrieved by the rigid nephroscope using atraumatic peanut forceps with minimal to no irrigation, keeping the patient tilted away from the surgeon to keep the fragments from falling back into the anterior and lateral calyces.

On occasion the Perc-N-Circle device (Cook Urological) can be invaluable for retrieving stones from otherwise inaccessible calyces via the rigid scope (Figure 21.11). This unique device is a 5-mm coaxial semi-rigid instrument with a tipless, large nitinol basket on the distal aspect. Deployment of the basket into a calyx is usually possible as long as the infundibular neck of a calyx can be directly visualized, even if the neck is too small or too peripheral to allow direct access with the scope. Using a combination of direct vision or fluoroscopy, stones can be readily insinuated into the basket and retrieved by pulling them out through the infundibulum. If the neck is too tight to allow stone removal, it is a relatively simple task to open the basket and disengage the stone.

Obtaining safe percutaneous access and preventing ureteral stone migration

During PCNL the coaxial Accordion™ device (Figure 21.12) can serve several purposes. It is usually placed in the collecting system over a guidewire at the beginning of the case and deployed at the UPJ. Since the lumen of the device accommodates a 0.38-inch guidewire, it is ideal for performing urine sample collection as well as retrograde pyelography. Once it is deployed at the UPJ, it is very effective in preventing stone migration down the ureter, obviating the need for ureteroscopy at the end of PCNL [27].

Intercostal renal access during PCNL and other percutaneous renal procedures is associated with an increased incidence of pneumothorax, hydrothorax, or hemothorax postoperatively. The Accordion device can be used to prevent upward migration of the kidney in situations when intercostal access initially appears unavoidable, allowing establishment of a more favorable subcostal renal access (Figure 21.13). Deployment of a coaxial film-based occlusion device at the UPJ can be used to gently hold the kidney in its lower position during ventilation, and in this position percutaneous needle placement can be obtained without the need to go above the ribs. This method provides an effective way to obtain more favorable percutaneous access, potentially avoiding complications associated with intercostal renal access. Due to the atraumatic nature of this device, it has been confirmed endoscopically that

Publisher's Note:

Figure 21.12 Coaxial Accordion device deployed at ureteropelvic junction (reproduced with kind permission from Percsys).

there are no injuries at the UPJ when it is used to provide gentle traction [28].

Specific techniques

Infundibular stenoses

Infundibular stenoses are characterized by a narrow infundibulum leading to a dilated or nondilated calyx with or without stone(s) [29]. They can be caused by extrinsic compression by malignancy or retroperitoneal fibrosis, or intrinsic narrowing from tuberculosis, chronic stones, infection, or scarring. It is rarely caused by a crossing segmental artery, known as Fraley's syndrome [30]. This condition can cause flank pain, hematuria, and deterioration of renal function. Surgery of infundibular stenosis generally involves percutaneous access into the hydrocalyx, but occasionally an anterior calyx is accessed or it cannot be reached percutaneously. In these instances flexible nephroscopy can be helpful.

The two indications for treating an infundibular stenosis are relief of obstruction (dilated calyx) or a retained stone (calyx may be dilated or not). It should be noted that defining an infundibulum as stenotic is a relative distinction in that some infundibular stenoses may not truly be causing obstruction (no dilation of the calyx beyond) but are simply too small to accommodate a ureteroscope or nephroscope. In the latter situation, the main indication to surgically open the infundibulum would be for diagnosis (e.g. ruling out transitional cell

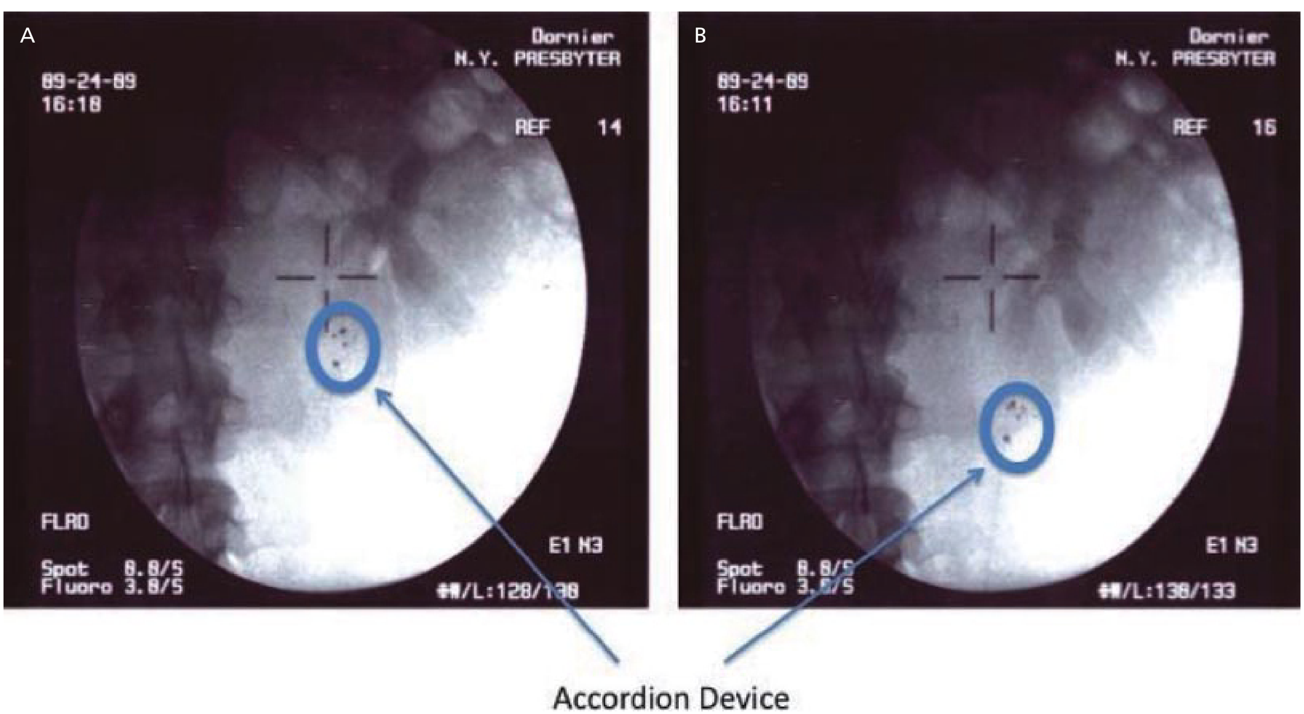

Figure 21.13 Accordion device (Percsys, Palo Alto, CA, USA) preventing upward migration of the kidney.

carcinoma in a patient with positive cytologies) or treatment of a pathology in the calyx above (e.g. stone or tumor).

Our technique first involves cannulating the infundibulum with a guidewire if it is extremely tight. A hydrophilic-coated guidewire is preferable for this since it can readily be coiled in the calyx beyond. The reason for placing this guidewire if the stenosis is very tight is that in the course of incision a false passage can inadvertently be created and the true opening obscured by a flap. If this occurs, access to the calyx is lost and complete obstruction could result. If the stenosis is approachable with a rigid scope, the peanut forceps can occasionally be used to gently dilate the infundibulum enough to permit subsequent entry with a flexible scope. Alternatively, a holmium:YAG laser or balloon (6 mm × 4 cm) can be used. If the stenosis is approachable only with a flexible scope, a holmium:YAG laser can be directed to the affected area. The infundibulum is then incised inferiorly and superiorly, as anatomic studies have shown less blood supply in these areas (Figure 21.14) [30].

A balloon can sometimes be used instead or in addition to the laser. The proximal end of a double pigtail stent can be placed in the hydrocalyx and often a stent is then placed across the newly opened area and left for 4–6 weeks. The size of the stent does not affect the eventual patency of the infundibulum [31].

If there is a stone in the hydrocalyx above a stenosis, the preferable approach is to open the infundibulum wide enough to permit intact retrieval of the stone. The reason for this is that any fragments created can become lodged in the incised tissues, potentially creating an inflammatory response that could promote restenosis. Thus, all stones from the collecting system should be cleared before treating a stenotic infundibulum.

Figure 21.14 Incision of the stenotic infundibulum.

Possible complications of this approach include bleeding and eventual restenosis. As mentioned previously, the incisions should be made superiorly and inferiorly, and an effort should be made to maintain hemostasis at the time of surgery. Hemostasis can be achieved by defocusing the laser (i.e. increasing the distance from the tip of the fiber to the tissue) to create a blanching (coagulation) of the bleeding tissues. If this is not effective, then a bugbee electrode can be used with a coagulation setting of 20 W to achieve hemostasis. The downside of using a bugbee is that there is a higher likelihood of restenosis due to cicatritial contracture and ischemia. If bleeding is still present, a large caliber stent or nephrostomy tube can be placed across the infundibulum to aid in tamponading the area.

Excluded calyx

Occasionally an infundibular stenosis will be so severe that the calyx closes off completely and there is no communication between it and the renal pelvis. This condition is often diagnosed when a patient has an area of obvious hydronephrosis and no contrast flows into the expected calyces on a retrograde pyelogram [32].

There are three alternative treatments for this condition. First is retrograde ureterorenoscopy with laser incision. This is usually blind since no infundibulum can be visualized. Sometimes there is a slight dimple or area of scarring that provides a hint that an infundibulum was previously present. It is very helpful to know if the invisible hydrocalyx is anteriorly or posteriorly located in order to guide where the incision should be made. Most commonly, the affected calyx is the posterior upper pole calyx and therefore the incision should be made at the 6 o'clock position in the most superior location of the renal pelvis. This technique can lead to significant parenchymal bleeding and a bugbee electrode (a 2F electrode is preferred because it permits adequate irrigation) should be readily available.

The other two techniques involve percutaneous access. The indirect approach is particularly useful for anteriorly located excluded calyces and involves access to the opposite pole of the excluded calyx. If the excluded calyx is located in the upper pole, a lower pole posterior calyx is accessed and if it is in the lower pole the superior pole posterior calyx is accessed. After visualizing the renal pelvis, the excluded calyx is entered with either a laser or peanut forceps. This approach can be aided by placing a needle into the excluded calyx under

ultrasound guidance and instilling contrast to help fluoroscopically guide the incision.

The preferred approach to an excluded calyx that is posteriorly located, however, is a direct percutaneous approach [12]. An open-ended catheter is placed into the renal pelvis close to where the original infundibulum is suspected to be. A needle is now placed percutaneously and directed toward the tip of the ureteral catheter in two planes. If the excluded calyx is in the upper pole, the needle is placed through the upper pole of the kidney into the renal pelvis. If the calyx is in the lower pole, then the needle is placed through and through the lower pole of the kidney until the renal pelvis is accessed and clear fluid obtained. A super-stiff Amplatz-J wire is coiled in the renal pelvis, and then the tract into the renal pelvis is dilated with a fascial dilator and then with a balloon-dilating catheter. Almost invariably the percutaneous tract goes through the excluded calyx and the technique is successful in creating a large neoinfundibulum. If significant bleeding is encountered, fulguration can be performed with a rollerball electrode. To keep the neoinfundibulum open, the preference is to simultaneously place two parallel ipsilateral stents (6F or 7F) that coil proximally in the excluded calyx and distally in the bladder. Alternatively, a large-bore Foley catheter can be placed through the neoinfundibulum with the balloon in the renal pelvis and a side hole created to drain the calyx. However, this is usually uncomfortable for the patient and is impractical to maintain for the 4–6 weeks that are required for healing.

Symptomatic renal cysts

Renal cysts are often discovered incidentally on routine imaging for other indications and are usually asymptomatic. Occasionally, a parapelvic cyst may become so large that it causes distortion of the collecting system and obstruction of the renal calyces [33]. These obstructing parapelvic cysts will often cause flank pain and need to be ablated using a laparoscopic technique or a percutaneous approach. During PCNL, an asymptomatic exophytic or parapelvic cyst may need to be ablated or simply drained in order for the surgeon to access the calyx with the stone.

The preferred approach to treat these parapelvic cysts depends on the aim of treatment. For instance, if a parapelvic cyst is asymptomatic but obstructs access to a calyx, it is relatively simple to drain the cyst with a needle to restore the normal renal anatomy. Once the normal renal anatomy is restored, it is possible to puncture into the intended calyx as usual. If the cyst is not aspirated first, the tract is dilated and the cyst is unintentionally entered with the nephroscope, it may be impossible to navigate into the collecting system.

To ablate the cyst directly, initially a ureteral catheter is placed for retrograde pyelography in the supine position, then the patient is turned prone as for a PCNL. The distortion of the calyces from the parapelvic cyst is confirmed with retrograde pyelography. An 18G spinal needle is placed into the cyst transparenchymally using the triangulation technique. The tract is balloon dilated to 30F, and a 30F Amplatz sheath is placed in the cyst. With a standard continuous flow 26F resectoscope with a rollerball or loop, the cyst wall is fulgurated using electrocautery. In some instances, cyst wall can be harvested for analysis. Also, portions of the cyst wall can be excised to marsupialize the cyst into the retroperitoneum or the collecting system. Patients are usually left with a drainage tube in the cyst itself, which is removed in 1–2 days [34].

Bipolar rather than monopolar electrocautery is now preferred to ablate the symptomatic parapelvic cyst and prevent recurrence. Bipolar electrocautery has been studied in the management of benign prostatic hyperplasia, and a major advantage of this technique is the ability to use isotonic saline as the irrigant solution with minimal changes in serum sodium despite long operative times [35–37]. Percutaneous ablation of parapelvic renal cysts with electrocautery has been shown to be effective with minimal morbidity [34]. Since absorption of irrigant during percutaneous procedures can be high, the use of bipolar electrocautery and isotonic saline irrigation during percutaneous ablation of symptomatic parapelvic cysts is preferable.

In our experience, percutaneous ablation of symptomatic parapelvic cysts using bipolar electrocautery is safe, and causes significantly less postoperative hyponatremia compared to a monopolar electrocautery system (Figure 21.15). It also appears to have an efficacy similar to that of the monopolar system [37].

Conclusions

Advances in flexible nephroscopy and instruments available for percutaneous renal procedures have made it possible to perform surgery more efficiently and safely. Many of the instruments and techniques discussed increase access to difficult calyces during percutaneous renal procedures and reduce the need for additional percutaneous access. Flexible nephroscopy is also helpful in cases of infundibular stenosis, excluded calyces, and symptomatic parapelvic cysts to improve drainage and reduce infection and stone formation. It is hoped that the techniques outlined in this chapter will help urologists to expand their indications for flexible nephroscopy, increase their comfort level with new scopes and accessories, and attempt the techniques before adding another access during a difficult percutaneous renal procedure.

CHAPTER 22

Percutaneous Treatment of Ureteral Stones

Oscar Schatloff, Amir Cooper & Yoram I. Siegel

Endourology Unit, Tel Aviv University Sackler School of Medicine, Urology Department, Assaf Harofeh Medical Center, Zerifin, Israel

Indications (Table 22.1)

Percutaneous antegrade ureteroscopy is an exceptional treatment modality for ureteral stones and is indicated when extracorporeal shock-wave lithotripsy (ESWL) or retrograde ureteroscopy (URS) are anticipated to have low success rates or increased risk of complications, or when they are not possible due to anatomic variations or abnormalities.

ESWL is a first-line treatment for ureteral stones regardless of their size and location [1]. However, success rates are highly dependent on the size and location of the stone, shock-wave technique, and patient characteristics, with best results achieved for stones of less than 10 mm in diameter located in the upper ureter [2–6].

URS is the preferred treatment for ureteral stones greater than 10 mm in diameter [1, 7–9]. It has demonstrated higher success rates than ESWL, albeit at the expense of slightly higher complication rates. While initially restricted to the distal and mid ureter, advances in instrumentation and ablation technology enable current scopes to reach and treat stones along the entire ureter, regardless of their size or composition. Stone location in the upper ureter, stone impaction, and procedure performance by a nonendourologist have been most consistently associated with decreased stone-free and increased complication rates such as ureteral injury and stricture [10].

Although the great majority of patients with ureteral stones will be treated by either URS or ESWL, specific cases may be better approached percutaneously (Figure 22.1). As a general concept, the more discouraging a setting is for retrograde URS, the more attractive it is for antegrade access, as in the cases of large stones with proximal hydroureteronephrosis (Figure 22.2), altered anatomy, concomitant ureteral and renal stones, severe stone impaction, presence of distal ureteral stricture or tortuousness (Figure 22.3), ESWL or URS failure, previous urinary diversion, or nonrefluxing ureteroneocystostomy, or any combination of the above [11–19].

A typical candidate for the antegrade approach is a patient with a large (≥15 mm diameter) and impacted upper ureteral stone with concomitant proximal hydronephrosis. A dilated upper ureter enables removal of intact stones and repetitive easy fragmentation. There is no risk of proximal fragment migration, and synchronous kidney stones can be easily cleared during the same session. Distal migration is not common, as the ureter below the stone is usually not dilated, but when it does, it can be easily managed with flexible antegrade ureteroscopy, and stone extraction through a dilated proximal ureter.

Patients with urinary diversions or nonrefluxing ureteroneocystostomy are attractive candidates for an antegrade or combined (antegrade and retrograde) approach. Difficulties in finding the ureteral orifice, accessing the ureter (especially on the left side), and negotiating through a floppy bowel, as in cases of ileal conduit and especially in neobladders, make the purely retrograde approach extremely difficult to accomplish. Percutaneous access is the preferred alternative, as some degree of hydronephrosis is usually present, and nephrostomy tubes for decompression, harbored by many patients, can be used as an access to the kidney. The procedure can be performed completely with an antegrade approach, or a percutaneously placed guidewire

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

can be used to guide a flexible ureteroscope from below (combined approach). Should incision of ureteroenteric strictures or stone extraction be needed, they are best achieved from above.

Preoperative evaluation

Preoperative evaluation is directed to three main points: burden of stone disease, anatomy of the upper tract, and general patient status. In most cases, the first two aspects are assessed with noncontrast helical computed tomography (NCHCT). Stone size and location, together with additional renal stone burden, are revealed with precision. Calyceal and ureteral anatomy is also clearly evidenced. In the modern endourology era, the CT scan has completely displaced intravenous pyelography (IVP) as the preferred test for preoperative planning [20, 21]. The main advantages of CT are comprehensive three-dimensional (3D) assessment of the intrarenal collecting system anatomy and the relation of the kidney to adjacent intraperitoneal and retroperitoneal organs and vasculature.

If the patient has undergone previous URS, operative reports should be retrieved and relevant information taken into consideration. Intraoperative complications and stone impaction are of special interest. If either of these was present, the possibility of ureteral stricture (usually at the original stone location) should be highly suspected and proper intraoperative evaluation and

Table 22.1 Indications for percutaneous antegrade ureteroscopy.

Large, impacted upper ureteric stone
Simultaneous kidney stones
Failure of retrograde ureteroscopy (URS) or extracorporeal shock-wave lithotripsy (ESWL)
Presence of distal ureteric stricture or severe tortuosity
Presence of urinary diversions

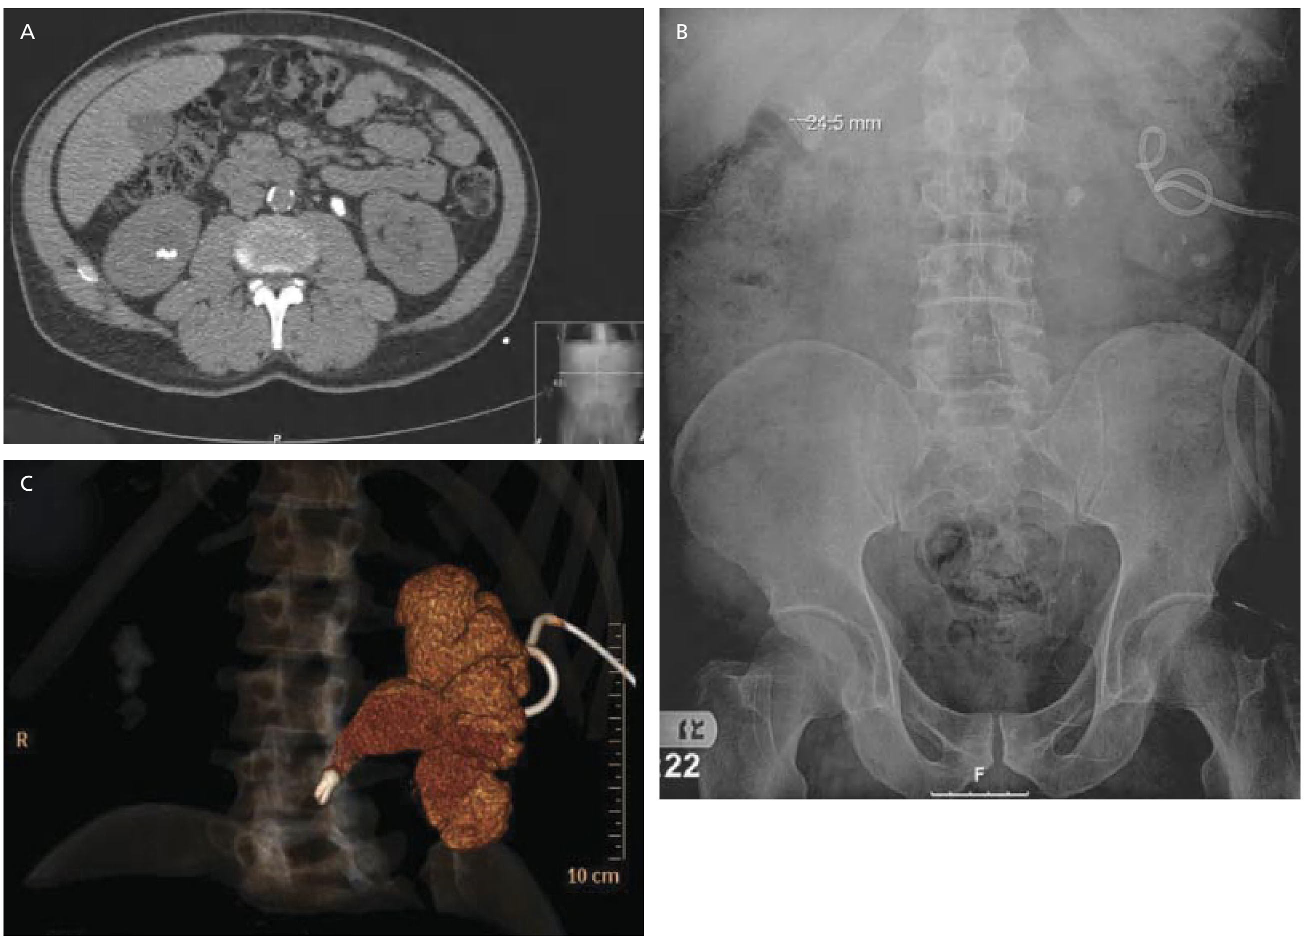

Figure 22.1 Upper ureteral impacted stone and complete obstruction. (A) Noncontrast computed tomography with left hydronephrosis and upper ureteral stone. (B) Upper ureteral stone on kidney, ureters, and bladder X-ray with left nephrostomy placed in the lower pole. (C) 3D reconstruction of antegrade pyelography demonstrating stone impaction with complete obstruction.

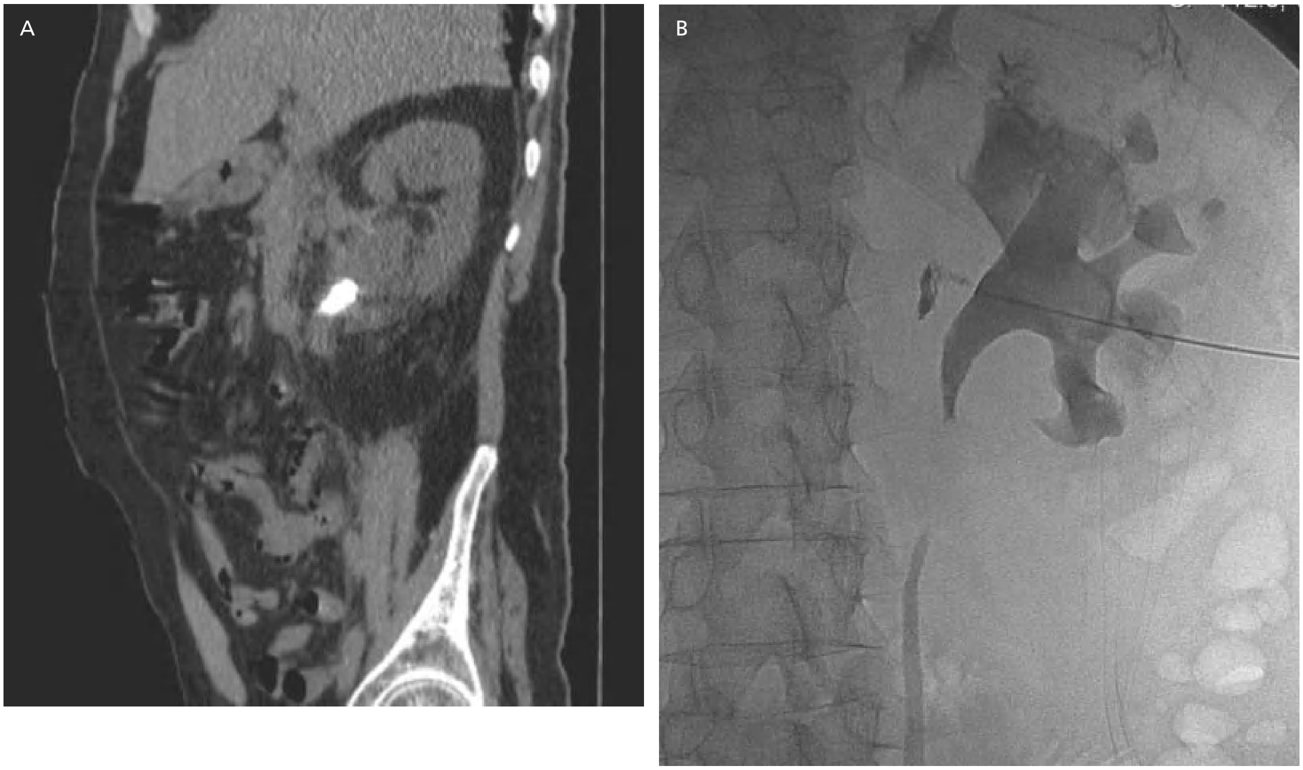

Figure 22.2 Upper ureteral stone obstruction. (A) Noncontrast computed tomography with large radiolucent impacted stone. The stone is not seen on kidney, ureters, and bladder X-ray. (B) Antegrade pyelography demonstrating upper ureter with radiolucent stone impaction.

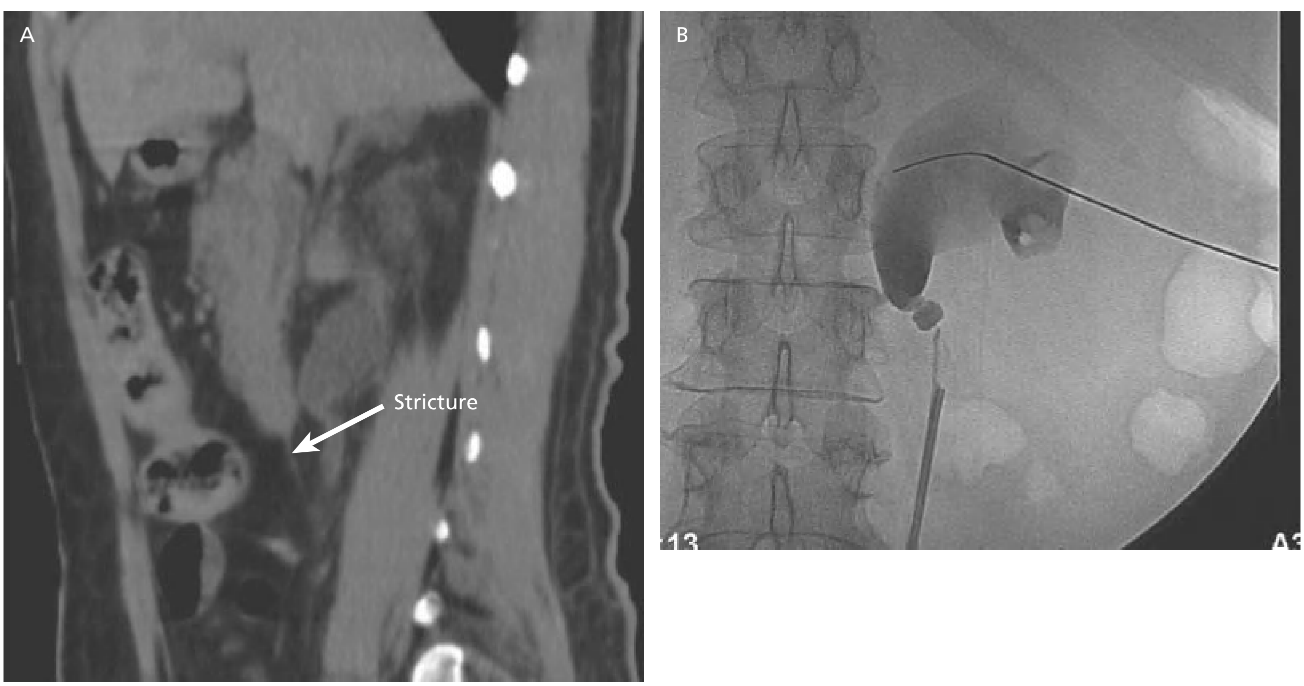

Figure 22.3 Upper ureteral stricture. (A) Noncontrast computed tomography with dilated renal pelvis and stricture (arrow) in the upper ureter. (B) Combined antegrade and retrograde pyelography with upper ureteral stricture.

treatment undertaken. [22] A prior nephrolithotomy or percutaneous nephrolithotripsy could indicate a more challenging percutaneous access due to perirenal fibrosis, scar formation, or calyceal infundibular stricture. Gaining access in such cases can require metal dilator sets.

General patient status focuses on assessing cardiovascular and pulmonary tolerance to prolonged prone position, anemia and coagulation disorders, renal function, and current and previous urinary tract infections (UTIs). Anesthetic clearance should be obtained for patients with known cardiovascular or pulmonary disease and UTIs should be treated accordingly. Pulmonary function tests are helpful to access the feasibility of the face-down position, especially in obese patients. The supine position is a desirable alternative for severely obese patients or those with chronic obstructive pulmonary disease (COPD); and a semirotated torso positioning allows for a combined antegrade and retrograde approach [23, 24]. A preoperative nephrostomy can save time in such instances. Warfarin should be stopped or the patient switched to low molecular weight heparin with anticipation; the last dose of the latter should be administered 12 h prior to the procedure.

In patients with impaired renal function or parenchymal loss apparent on CT, nuclear renal scintigraphy should be obtained. A static renal scan (DMSA) can precisely assess differential renal function even in the presence of obstruction [25–27]. If split kidney function is less than 15% and does not improve with renal drainage then laparoscopic nephrectomy with ureterectomy below the stone level is advisable instead.

The patient is left on nil per os (NPO) from midnight the evening prior to the procedure, and blood type and cross-matching are obtained should transfusion be required. Autologous blood donation is not cost-effective, and routine bowel preparation is not performed, as bowel injury is infrequent [28, 29].

Surgical technique and instrumentation (Table 22.2)

After induction of general anesthesia, the patient is placed in the lithotomy position and a 6F open-ended ureteral catheter is inserted up to the renal collecting system under fluoroscopy to assure uncomplicated ureteral catheter access to the collecting system. This also can be achieved with a flexible cystoscope and in the prone position. If there is no passage, then the ureteral catheter should remain below the stone or stricture for careful contrast injection, without causing any perforation. A retrograde pyelography can fill up the upper system to facilitate the kidney access. The ureteral catheter is connected to an extension tube and a Foley catheter is subsequently left in the bladder.

Table 22.2 Steps of percutaneous antegrade ureteroscopy.

Retrograde insertion of open-ended ureteral catheter
Posterior upper pole or mid–upper pole puncture
Insertion of thin Amplatz sheath or ureteral access sheath up to the level of the stone
Flexible or semi-rigid ureteroscopy
Flexible nephroscopy if the stone is just below the ureteropelvic junction (UPJ)
Laser lithotripsy and basket extraction
Tube or tubeless as evaluated intraoperatively

The patient is turned to the prone position, carefully padded, and a hard-surface pillow is placed under the abdomen to allow proper chest expansion (see Video 22.1). If the patient harbors a nephrostomy tube (usually placed due to sepsis or renal function impairment), a ureteral catheter is not needed as the nephrostomy tube can be used to inject contrast into the collecting system; only a Foley catheter in the bladder is necessary. After sterile preparation, a mixture of contrast and/or air is injected through the ureteral catheter to aid in the identification of the most suitable posterior calyx for puncture. If retrograde pyelography is not feasible, then access is obtained under ultrasound guidance. If rigid instruments are used, the selected calyx must allow straight alignment with the ureteropelvic junction (UPJ). This is usually accomplished by puncturing an upper or mid–upper calyx [30, 31] with an 18G Chiba needle. After entry into the chosen calyx is confirmed, a floppy-tip 0.035-inch hydrophilic wire is coiled in the collecting system, the skin is incised, and the needle shaft removed. Examples of appropriate guidewires for gaining access are the Roadrunner (Cook Medical, Bloomington, IN, USA) and glidewire (Terumo Medical, Somerset, NJ, USA). Hydrophilic guidewires with a floppy tip and rigid shaft (although some are slippery) can also be used, and include the Sensor guidewire (Boston Scientific, Natick, MA, USA) and stiff shaft glidewire (Terumo Medical).

The tract is sequentially dilated with 6F, 8F, and 10F fascial dilators. Should the wire not go down the ureter, an attempt to guide the wire down to the ureter is made with a 6F angiographic catheter. If successful, the floppy wire is replaced by a super-stiff wire and coiled in the bladder. If unsuccessful, no force should be exerted as this may result in unnecessary and disturbing bleeding or perforation. A second wire should be placed and coiled in the renal pelvis or calyx for safety. If the aim is to dilate up to 30F, balloon or Amplatz dilators are equally effective [32, 33]. In most cases a mini-access sleeve is needed; an 18–20F access sleeve is sufficient for a ureteroscope or flexible nephroscope (see Video 21.1). We usually dilate up to 18F when using just a flexible

nephroscope, and 12–14F when using just a flexible ureteroscope. While stones located in the upper ureter near the UPJ can be reached with a flexible nephroscope or semi-rigid ureterosope, those located more distally require especially flexible ureteroscopy. In the case of a unique ureteral stone with no concomitant renal stones, we usually use a flexible ureteroscope, and advance a 12F ureteral access sheath down to the ureter to gain safe direct ureteral access. If a previous nephrostomy tube was placed for acute reasons, the tract can be used to access the collecting system. However, the procedure should be performed only after the acute state has been resolved, usually about a week later. Flexible scopes are required to access the ureter if the nephrostomy tube was placed through a lower pole calyx. When a straight approach to the UPJ is desired, a new upper or mid–upper pole puncture is required. In such cases, use of the nephrostomy tube to fill the collecting system with contrast and air can aid in the selection of the best calyx for puncture. Direct and straight access to the UPJ is crucial, and thus should not be compromised by using the pre-existing nephrostomy tract.

Lithotripsy can be performed with different modalities, including ultrasonic, mechanical, and laser energy. While ultrasonic lithotriptors enable concomitant fragmentation and suction, they can be deployed solely through semi-rigid endoscopes. Lasers on the other hand, can be deployed either through rigid or flexible scopes, and are the preferred modality with small-diameter flexible ureteroscopes. Fragments are extracted with graspers or baskets. Nitinol-covered baskets deployed through flexible scopes are recommended as they least impede scope deflection. We perform ureteral lithotripsy with a holmium:YAG laser and a 200-μm fiber when working with a flexible ureteroscope, and with 365-μm fiber or mechanical lithotripter (Lithoclast, EMS) when working with a semi-rigid scope or flexible nephroscope. Special care should be taken to clean all stone fragments in the obstructed area (see Video 21.1), since residual stone material can aggravate stricture formation. A ureteral dilator is passed down the ureter over a guidewire following stone removal to ensure appropriate ureteral caliber. If ureteral stricture is detected, an endoureterotomy using the holmium laser is feasible, set at a higher frequency and intensity than the lithotripsy set-up.

The need for postoperative drainage is evaluated intraoperatively [34]. If the patient is a candidate for a "tubeless" procedure, we place a double-J stent antegradely [35, 36] with stitch closure of the puncture site (see Video 21.1); if not, a re-entry percutaneous nephrostomy can be used for rapid reaccess to the ureter, or a Nephro-stent. If needed, we leave a 5F ureteral catheter down the ureter through an 18F Foley catheter with a hole in the tip located at the renal pelvis, for drainage and antegrade pyelography, or re-entry access.

Postoperative care

The retrograde ureter catheter can be removed postoperatively. The patient resumes a regular diet the same or next day, according to tolerance. If a tubeless procedure was performed, the patient is discharged on postoperative day (POD) 1 and stent removal is scheduled approximately 10 days later. If only a nephrostomy tube was left in, an antegrade nephrostogram is performed on POD 2 and the nephrostomy removed upon assurance of contrast passage to the bladder.

Results

Contemporary stone-free rates for percutaneous antegrade treatment of ureteral stones are at least 86% [37–39]. In a randomized trial of patients with upper ureteral stones of greater than 1 cm in diameter, Sun *et al*. found a significantly higher stone-free rate with the antegrade approach than with retrograde ureteroscopy (100% and 86% respectively, $P = .03$) [37]. A randomized study of 150 patients with upper ureteral stones of 1.5 cm or greater in diameter found no significant differences in stone-free rates between retrograde ureteroscopy, laparoscopic ureterolithotomy, and percutaneous antegrade ureteroscopy (76%, 90%, and 86% respectively, $P = .06$) [38]. The low statistical power of the study may be the reason for the lack of statistical significance, despite the trend.

A retrospective study of antegrade percutaneous ureteroscopy for upper ureteral stones of greater than 1 cm in diameter in 192 patients with severe hydronephrosis reported a 5% stricture rate [39]. A reported 44% stricture rate for retrograde ureteroscopy for upper ureteral stones was mostly due to ureteral injury and failure to completely release all stone fragments from the ureteral wall [22].

Conclusions

With high stone-free rates and minimal complications, percutaneous antegrade ureteroscopy is an excellent option when URS or ESWL are not suitable or have previously failed. Nevertheless, close postoperative follow-up is important to ensure early identification of ureteral strictures, regardless of the approach selected.

CHAPTER 23

Special Problems with Staghorn Calculi

Kevan M. Sternberg & Timothy D. Averch
Department of Urology, University of Pittsburgh Medical Center, Pittsburgh, PA, USA

Introduction

Staghorn calculi require definitive surgical management in order to prevent the potential consequences of renal deterioration from long-term obstruction and recurrent urinary tract infections (UTIs) and sepsis. According to the American Urological Association (AUA) guidelines panel (2004), complete stone removal should be the therapeutic goal, and percutaneous nephrolithotomy (PCNL) monotherapy has emerged as the treatment of choice for the majority of patients with staghorn calculi [1].

Varying percutaneous techniques have been developed with the goal of maximizing stone clearance while maintaining patient safety. Modifications have been described in patient positioning [2], site and number of percutaneous access tracts [3], and instrumentation used for endoscopy, stone fragmentation, and stone removal [4].

In addition to the steep learning curve required to perform PNCL, specific circumstances, including previous urinary tract surgery, paraplegia, and coagulopathy, can make complete stone removal more challenging. Significant stone burden can make both access and stone removal more technically demanding. Active infection can also be encountered unexpectedly, and this must be addressed in order to maximize patient safety.

This chapter will focus on patient- and stone-related variables that can complicate successful PCNL, review the varying described techniques used to overcome these challenges, and review our own approach in treating difficult staghorn calculi.

Preoperative evaluation

All patients scheduled for PCNL undergo standard preoperative laboratory testing and cardio/pulmonary evaluation based on age and pre-existing medical conditions. Preoperative urine cultures are mandatory to identify specific pathogens that can guide perioperative antibiotic coverage. These cultures are often difficult to interpret as many patients have indwelling ureteral stents or nephrostomy tubes already in place. Treatment of symptomatic patients with culture-specific oral antibiotics is mandatory prior to an elective procedure and we routinely treat asymptomatic patients with positive urine culture results to sterilize the urine prior to urologic instrumentation [5]. Patients who have unusual or resistant pathogens may require preadmission hospitalization for intravenous antibiotics prior to definitive therapy. Specific parameters regarding agent of choice and duration of perioperative therapy are often made in conjunction with our infectious disease colleagues. For asymptomatic patients with negative or colonized culture results, broad-spectrum antibiotics with adequate urinary tract penetration are preferred. In our practice, we most often utilize combination therapy with ampicillin (1–2 g) and gentamicin (5–7 mg/kg) to provide both Gram-positive and Gram-negative coverage. Alternatively, quinolones provide adequate coverage of urinary pathogens and can be used for patients with penicillin allergies. Cephalosporins can also be used in patients with mild penicillin allergies or in patients with renal insufficiency.

Figure 23.1 Air nephrogram used for identification of a posterior calyx.

Access

We perform all PCNL in the prone position using a split-leg table to provide access to the bladder. Flexible cystoscopy is performed and a guidewire is positioned in the renal pelvis under fluoroscopic guidance. A ureteral occlusion balloon (Boston Scientific, Natick, MA, USA) is then placed, followed by a Foley catheter to drain the bladder. The guidewire is removed and the posterior calyces are then outlined using air injected through the occlusion balloon to produce an air nephrogram (Figure 23.1). Normal saline irrigation is then instilled through the ureteral occlusion catheter to fill the collecting system and create a "pseudo-hydronephrosis." An access point (most commonly a posterior calyx) is then chosen based on stone location and overall burden to facilitate the most direct path to treat the stone burden.

After a site is chosen, percutaneous access is obtained using a standard triangulation method with an 18G Chiba needle. Access is confirmed using fluoroscopy as well as with the return of air and irrigation fluid from the needle lumen. A guidewire is then advanced into the renal pelvis with the primary goal of obtaining access into the bladder. Difficulties advancing the guidewire down the ureter can be encountered due to significant stone burden or stone impaction, most commonly at the ureteropelvic junction. In these situations, ureteral access may not be possible, and as an alternative, redundant guidewire is "curled" in the renal pelvis to facilitate tract dilation. Tract dilation can be performed via single-step balloon dilation or serial sequential dilation with either metal or Amplatz dilators [6]. In our institution, we currently use the X-Force N-30 (Bard, Covington, GA, USA) balloon dilation catheters. Tracts are dilated to 30 atm, and occasionally, fascial incising needles are needed secondary to dense scar tissue in order to achieve full tract dilation. Balloon dilation is the preferred method of tract dilation at our institution in an effort to decrease the risk of bleeding that has been associated with sequential dilation [7, 8]. In our recent review of 225 patients using balloon dilation for single tract access, the mean decrease in hematocrit was 6.1 ± 4.3%, and only three patients required perioperative blood transfusion [9].

In situations where there is limited space due to a large stone burden, it is imperative to carefully position the balloon so that it remains in the collecting system without displacing the stone, losing access, or perforating the collecting system. There are also circumstances in which a staghorn calculus fills the entire collecting system, leaving no suitable area to gain access. In these situations, we often proceed with prone flexible ureteroscopy. Stone is cleared to access a posterior, upper or mid pole calyx, using holmium laser lithotripsy. The ureteroscope can then be used to guide and visualize the needle entering the chosen calyx.

Urologist versus radiologist obtained access

The decision process in selecting the ideal calyx for access is fundamental in achieving the goals of maximal stone clearance and procedure safety. Often, preoperative or perioperative access is obtained by interventional radiologists for various reasons, including acute obstruction and/or infection, patient body habitus, atypical renal anatomy, prior urologic intervention/reconstruction, or surgeon preference. A survey from the University of Iowa in 2003 found that only 11% of urologists performing PCNL routinely obtained the percutaneous access [10].

A recent study from our institution compared outcomes and complications of access obtained by urologists and interventional radiologists in 233 patients undergoing PCNL [11]: 39% of the stones in the urologist access group were classified as staghorns versus 30% in the radiologist group. The complication rates were similar between groups, but the overall stone-free rate was significantly greater in the urology access group (99% vs 92.1%, $P = .03$). In cases of access performed by radiologists, additional urologist-obtained access was required in 36.8% of the cases. This is difficult to interpret as the primary goal of radiologist-obtained access was often to relieve acute obstruction, and not to facilitate future therapeutic management. Regardless, urologist-obtained access in high-volume stone centers can facilitate stone-free rates, ranging from 83% to 86%

[12, 13], even in the presence of very large stone burdens or staghorn calculi.

Supporting this notion, in a large retrospective series comparing PCNL outcomes in 1121 patients, El-Assmy *et al*. reported that between the urologist access group and radiologist access group stone-free rates (83.4% and 86.1%, respectively) and complication rates, except for bleeding (4.3% and 2.1%, respectively), were similar [12]. However, they observed that urologists utilized multiple (18.1% vs 0%) or supracostal tracts (16.9% vs 4.7%) more frequently, and concluded that urologist-obtained access is safe and effective even in cases of large or complex stone burdens.

Access location

Choice regarding the ideal calyx for percutaneous access is dependent on patient anatomy, stone burden, and individual surgeon preference. Accessing the upper pole allows for direct access to the majority of the collecting system as well as the upper ureter. This location is often necessary to treat staghorn calculi, large renal pelvic stones, and upper ureteric calculi [14, 15]. Upper pole access can be achieved via a subcostal or supracostal approach. Supracostal entry is usually in the 11th intercostal space. Although the upper pole often provides the most direct access to treat large or complex stone burdens, there is an increased risk of pulmonary complications, including hemothorax, hydrothorax, and pneumothorax, especially if an intercostal approach is utilized [15].

Several groups have examined the safety and efficacy of supracostal upper pole access [14–17]. They agree that this approach provides for excellent stone clearance while maintaining patient safety. In these large series, pulmonary complications ranged from 5% to 15%. When complications did arise, they were usually managed conservatively. In a comparative report, Lang *et al*. examined stone-free and complication rates utilizing both subcostal and supracostal percutaneous access [17]. Of 103 patients undergoing PCNL with intercostal access; 91 (88%) were rendered stone free, four had major complications, and six had minor complications. These results were compared to 39 patients with subcostal access; 29 (74%) were stone free, three had major complications, and eight had minor complications. From these data the authors concluded that intercostal access should be the route of choice for upper pole PCNL due to the low complication rate, high stone-free rate, and reduced operating time.

Lojanapiwat and Prasopsuk found that the supracostal and subcostal approaches were both effective with acceptable complication rates [14]. However, they observed a higher rate of pulmonary complications (15.3% vs 1.4%, $P < .001$ value) in patients undergoing supracostal access. Based on the potential for pulmonary complications, they recommend proceeding with a supracostal approach only in appropriately selected patients. Postoperative monitoring and chest imaging should be mandatory in these cases.

Single versus multiple access tracts

Treatment of complex or staghorn calculi can be approached with multiple percutaneous tracts during a single operative procedure [18, 19] or with a single tract approach in combination with flexible instrumentation [20]. It is controversial as to which of these approaches offers superior stone clearance while minimizing patient morbidity.

Utilizing multiple tracts in a single session is advocated by some authors because it is often difficult to access all of the renal calyces to treat the entire stone burden through a single tract. Stone-free rates in various series using multiple tracts are above 80% [19]. Described by Desai *et al*., main tract access is obtained via ultrasound guidance and is the site through which maximum stone burden can be cleared [18]. Additional supplemental tracts are placed for residual peripheral calyceal stones. Guidewires are placed to stabilize the tracts and the main tract is dilated to place a 26F or 28F Amplatz sheath. Secondary tracts are dilated later in the procedure to 20–24F. Lithotripsy is maintained for 90 min and a second stage is performed 48–72 h later if necessary.

Despite the potential advantages of improved stone clearance and less hospital cost with a single procedure, there are concerns with utilizing multiple percutaneous access points as well. The primary concern is for increased risk of intraoperative or postoperative hemorrhage and subsequent need for blood transfusion. Blood transfusion rates range from 3% to 45% in the literature with multiple tract access [19], although transfusion requirements have been shown to decrease with increasing surgeon experience [21]. Attempts to minimize the risk of bleeding have been addressed by limiting sheath size and dilating the secondary tracts later in the procedure only if needed. Guohua *et al*. describe a modification of multiple tract technique utilizing tracts dilated to 14–18F [22]. Using this approach, they obtained a stone clearance rate of 93% with a 3% transfusion rate.

Despite higher transfusion rates with the multitract approach, the risk of other major complications does not seem to significantly differ when compared to single tract procedures [18, 23]. Hegarty *et al*. have published the only study to date comparing the morbidities of these two approaches [23]. They reviewed 20 patients in each group and found that despite a higher transfusion rate in the multitract cohort, the mean drop in hemoglobin was similar between groups. They attribute this to the fact that the patients in the multitract group had significantly lower baseline hemoglobin values. Bleeding

can usually be managed conservatively, leading the proponents of this procedure to conclude that it is both safe and effective. Other proposed advantages include avoiding the increased cost and learning curve associated with the flexible instrumentation required in the single tract approach [19].

Large stone burdens can also be approached with a single access tract due to the technologic advances in flexible instrumentation, lasers, and basketing devices. This approach has been described by several endourologists [20] and is currently the procedure of choice at our institution. The access site is carefully chosen to provide access to the majority of calyces. Usually this is via the upper pole calyx, which enables the surgeon to access the majority of the collecting system. The most common access sites are either below the 12th rib or between ribs 11 and 12. After obtaining access and tract dilation, rigid nephroscopy is utilized to clear as much stone burden as possible, while minimizing renal parenchymal trauma. Our preference is to use the Lithoclast Ultra (Boston Scientific), which combines pneumatic energy to maximize stone fragmentation with ultrasonic energy to suction, remove stone fragments, and improve intraoperative visibility (Figure 23.2). Intracorporeal lithotripsy is an essential component of PCNL, especially when treating large stone burdens. The commercially available devices include ultrasonic and pneumatic devices, or a combination of the two. The advantage of the combination lithotripters is their ability to fragment stones of varying compositions while concomitantly evacuating stone debris. This avoids the time-consuming process of manual stone fragment removal [4]. The remaining stone burden is then approached with flexible instrumentation (Figure 23.3). Calculi that are small enough are removed with a stone basket via a flexible cystoscope or ureteroscope. Larger or impacted stones are fragmented with the holmium laser and then either removed with a stone basket or positioned so they can be treated with the rigid nephroscope.

At the conclusion of the procedure, we routinely leave either a single or double J ureteral stent. Historically, a large bore nephrostomy tube (22F council-tip catheter) was routinely placed to externally drain the kidney, maintain percutaneous access, and tamponade renal parenchymal bleeding. Now, a nephrostomy tube is placed only when there is concern for bleeding and residual stone at the conclusion of the primary procedure. The nephrostomy tube maintains the tract for second look nephroscopy. When there is minimal concern for bleeding or residual stone necessitating a second look procedure, our preference is to leave patients without a nephrostomy tube. While controversial, "tubeless" PCNL has been shown to be safe and effective while decreasing analgesia requirements and length of hospital stay [24, 25]. Recently, investigators have questioned the practice of tubeless PCNL. They prospectively studied patients undergoing tubeless PCNL versus early nephrostomy tube removal, and found no differences in analgesia requirements, mean decrease in hemoglobin, or hospital stay [26]. It is important to consider that complete stone removal may not always be achieved despite perceived on-table stone clearance, and maintaining the tract with a nephrostomy tube for second look nephroscopy may be beneficial.

Figure 23.2 Use of the Lithoclast Ultra (Boston Scientific, Natick, MA, USA) for rigid nephrolithotripsy.

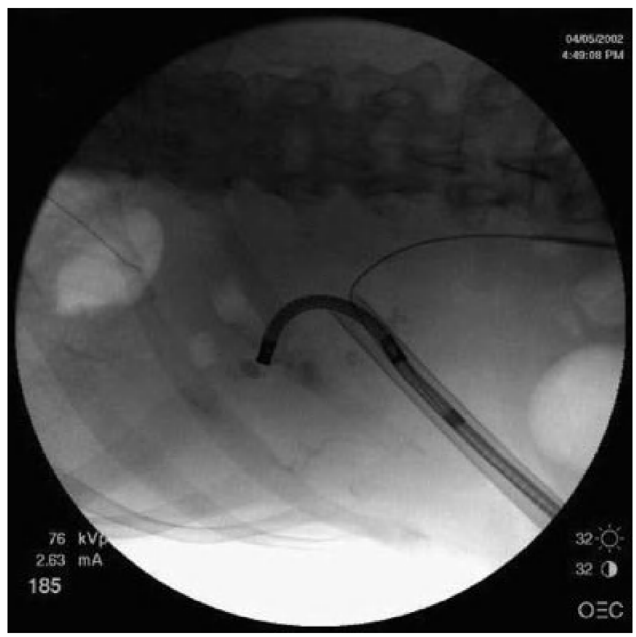

Figure 23.3 Use of the flexible cystoscope to treat remaining stone after rigid nephrolithotripsy.

If required, the timing of second look nephroscopy depends on primary surgeon preference. In a series of 45 renal units with a stone burden of 5 cm or greater undergoing single tract access, Wong and Leveillee reported a stone-free rate of 95%. This required a mean of 1.6 (range 1–3) procedures and second look nephroscopy was performed at 1 week when needed [27]. In our practice, a noncontrast computed tomography (CT) scan is obtained on the first postoperative day if there is suspicion of residual stone following the primary procedure. If residual stone is present, and the patient was left with a nephrostomy tube to maintain access, second look nephroscopy is performed on postoperative day 2 during a single hospital admission. If the patient was left tubeless, and residual stone is found, it can be approached with second-look retrograde ureteroscopy during the same hospitalization or at a later date depending on patient or surgeon preference.

Percutaneous access utilizing ureteroscopic assistance

Large stone burdens can make obtaining access difficult as there may not be sufficient space to enter and safely dilate a tract. If access can be achieved, and a tract is safely dilated, it may still be difficult to reach the entire intrarenal collecting system through a single tract despite the use of flexible instrumentation. To address these issues, retrograde ureteroscopy has been utilized to identify the ideal calyx for percutaneous entry [28, 29]. Ureteroscopy can be performed initially to assess the stone burden/location and to endoscopically clear a calyx to provide optimal access. Once identified and any obstructing stone burden cleared with retrograde lithotripsy, the access needle can be placed and confirmed under direct ureteroscopic vision [30]. Use of a ureteral access sheath can facilitate retrograde lithotripsy, which can be performed with the patient in either the supine or prone position. If done with the patient in the prone position, it is feasible to perform simultaneous retrograde and antegrade lithotripsy to maximize stone clearance (Figure 23.4).

Figure 23.4 Retrograde wire placement for initial prone ureteroscopy.

Supine versus prone percutaneous nephrolithotomy

Recently, there has been interest in the optimal patient positioning to maximize stone-free rates while minimizing the risk for position-related complications. This has resulted in an evolving debate comparing the outcomes of traditional prone PCNL with a modified supine position (Galdakao-modified supine Valdivia position) [31–33] (see Chapters 10 and 11). Proponents of the supine position stress the potential anesthesia advantages, particularly in obese patients, where the prone position can limit respiratory capabilities. Other perceived advantages include improved patient comfort and increased versatility of stone manipulation. Access is usually subcostal via a posterior lower pole calyx, which minimizes the risk for pleural injury. In addition, it has been stressed that by maintaining the supine position, retrograde ureteroscopy can be performed in addition to standard antegrade treatment. Ureteroscopy can be done prior to PCNL or simultaneously, and does not require patient repositioning which can be both time consuming and lead to increased pressure-related and neurologic injuries [32]. Scoffone *et al*. recently described their experience with endoscopic combined intrarenal surgery in the modified supine position. Their stone-free rate for 127 patients after a single procedure was 81.9%, and increased to 87.4% after a second look procedure. The mean stone size was 23.8 mm, and 33.1% were classified as partial or complete staghorn calculi. Their results led the authors to conclude that this approach was both safe and effective with an overall complication rate of 38.6%, which is in range with the current literature for PCNL [33]. No adjacent organ injuries, pleural injury, kidney loss, or deaths were reported.

Proponents of the prone position focus on the familiarity of the patient anatomy as well as decreased renal mobility facilitating percutaneous access. A comprehensive review of the literature by de la Rosette *et al*. concluded that prone PCNL is associated with decreased operative times, similar bleeding rates, and slightly improved stone-free rates for obese patients and staghorn calculi when compared to the supine approach

[31]. The only prospective randomized trial, by De Sio *et al*., found similar stone-free and complication rates between the two approaches, but their cohort excluded complicated and staghorn calculi, which limits the interpretation or applicability of their results [32].

To utilize the advantage of concomitant retrograde ureteroscopy, it is our preference to perform ureteroscopy in the prone position when required. Using a split-leg table, the patient can be positioned to easily perform flexible cystoscopy and access the ureter. Prone endoscopy has a steep, but easily overcome, learning curve, and this skill can easily be obtained by any endourologist familiar with flexible instrumentation. The prone position can thus allow for both antegrade and retrograde stone manipulation without the need for patient repositioning.

To support the feasibility of prone retrograde ureteroscopy our group recently reviewed 35 patients who were scheduled for prone ureteroscopy with the possibility of PCNL; 80% of the patients were able to be managed ureteroscopically while the remaining patients required additional percutaneous lithotripsy to maximize stone clearance. Of those treated only with retrograde ureteroscopy, 82% were rendered stone free. The seven patients requiring simultaneous PCNL were all stone free upon completion [34]. There were no serious complications in either group. It is now our practice to offer this approach for patients with characteristics that place them at high risk for morbidity with PCNL, including morbid obesity, previous urinary tract reconstruction, and paraplegia, or for patients who may be amenable to retrograde clearance, but in whom stone size, composition, and location may dictate an "on the table" decision.

Obesity

It has been theorized that PCNL in obese patients might be associated with lower efficacy or higher complication rates when compared to patients of normal weight. General anesthesia is one concern due to the limited respiratory pattern while patients are maintained in the prone position. Instrument size limitations pose potential technical concerns. The X-Force N-30 (Bard) balloon dilation catheters routinely used at our institution provide access sheath lengths of 17 cm or 22 cm. The working length of our longest rigid nephroscope is 24 cm. If the distance from the patient's skin to the desired access calyx is beyond these lengths, both access safety and efficacy of stone clearance can be significantly hampered. We routinely measure this distance using preoperative CT imaging to estimate whether our instruments can be effectively used. If the estimated distance is too long, staged flexible ureteroscopy will be the treatment recommendation.

While some early series reported higher complication rates and longer hospital stays in obese patients [35], the majority of studies have shown similar efficacy and complication rates for obese and normal weight patients [36–40]. In a recent review of our own institutional experience in 234 patients, stone-free rates, complication rates, blood loss, and length of hospital stay were all found to be independent of body mass index (BMI) [40]. The consensus from the majority of the published literature is that obesity in itself should not be a contraindication to a percutaneous approach in the hands of well-trained endourologists.

Infected systems

An important consideration in the management of complex stone burdens, especially staghorn calculi, is the presence of active infection. Preoperative work-up must always include urine culture and sensitivities, and when positive, complete treatment prior to surgery to sterilize the urine. Often this can be done as an outpatient with oral antibiotics; however, some patients can have resistant species of bacteria or fungi that require intravenous therapy. These patients may require preadmission and consultation with infectious disease specialists prior to definitive intervention. Since PCNL is most often an elective procedure, it is well established that patients with symptomatic UTIs should not undergo endourologic intervention due to the risk of septicemia. Such patients need to complete a full course of preoperative antibiotic therapy tailored to individual organisms and in some cases drainage of the infected/obstructed systems prior to definitive stone management.

Unfortunately, it is not possible to identify all patients at risk of infectious sequelae based on preoperative cultures and imaging. To further complicate this, purulent fluid may be encountered when the collecting system is entered during PCNL access. This can occur in asymptomatic patients with negative urine cultures. While the initial response would be to abort the procedure and drain the system due to the risk of urosepsis, the significance of encountering purulent fluid in an asymptomatic patient is unclear. Two groups of investigators recently examined this issue with the hypothesis that not all purulent fluid represents active infection [41, 42]. They postulated that in specific circumstances this phenomenon may represent a sterile inflammatory response to the presence of the stone or stone debris itself. Both groups retrospectively compared patients whose procedure was completed at the time of encountering purulent fluid versus those who were drained and treated at a later date. The incidence of urosepsis did not differ between the two groups, and Hesseini *et al*. concluded that PCNL can be performed in the same setting with appropriate antibiotic coverage [42]. Aron *et al*. further identified risk factors for sepsis which included recent

history of febrile UTI, borderline elevation of total leukocyte count, thick purulent fluid, use of a single tract or delayed creation of second tracts, and operating time greater than 90 min [41]. Despite these factors however, it remains impossible to predict which patients will progress to significant sepsis. Therefore, all patients must be closely monitored postoperatively whether the procedure is done in one setting or in a staged fashion. The optimal management of patients found to have purulent fluid on percutaneous access remains unclear without randomized studies. It is our practice to drain purulent systems and delay stone manipulation to a later time, even in asymptomatic patients. However, the optimal time period needed for collecting system drainage and antibiotics before stone treatment is unknown and currently determined by the judgment and experience of the primary surgeon.

Postoperative fever can often be the first clinical sign that patients may be becoming septic. However, while fever after PCNL is common, there is no direct correlation with progression to urosepsis and currently its clinical significance is unclear. It is clear that endoscopic stone manipulation can induce bacteremia, endotoxemia, and resulting sepsis in both healthy and immunocompromised patients. Cadeddu *et al*. recently reviewed patients undergoing PCNL with negative preoperative cultures who received prophylactic antibiotics. All patients who were febrile post PCNL remained hemodynamically stable with negative blood and urine cultures [43]. There was also no association with fever and stone composition. It therefore remains difficult to define patients who will become septic despite close postoperative monitoring.

Conclusions

PCNL for staghorn calculi or complex stone burdens can be technically challenging, even in the hands of experienced endourologic surgeons. Specific challenges include obtaining access, defining the optimal number and location of access tracts, the ideal patient positioning, and predicting and managing infectious complications. The goals of patient safety and efficacious stone removal remain clear. However, the ideal methods to achieve these goals are less clear and are the source of considerable debate. Future prospective studies comparing these techniques are necessary in order to provide definitive recommendations in the management of staghorn calculi. Until then, surgeon experience will remain the most important factor used to guide contemporary practice patterns with complex PCNL.

CHAPTER 24

Percutaneous Lithotripsy and Stone Extraction

Michael S. Lasser & Gyan Pareek

Brown University Medical School, Rhodes Island and Miriam Hospitals, Providence, RI, USA

Introduction

Currently, percutaneous nephrolithotomy (PCNL) employs four techniques for intracorporeal lithotripsy in clinical practice: electrohydraulic lithotripsy (EHL), ultrasonic lithotripsy, pneumatic lithotripsy, and laser lithotripsy (Figure 24.1). Each of these lithotripsy devices has inherent benefits and limitations to their utilization. PCNL remains the procedure of choice for most stones greater than 2 cm in size, complex staghorn calculi, some lower pole stones, stones within a caliceal diverticulum, and larger renal stones that are refractory to extracorporeal shock-wave lithotripsy (ESWL) [1].

Once a stone has been adequately fragmented, extraction is necessary in most situations. Several lithotripsy devices, specifically ultrasonic lithotripsy, have been paired with suction for simultaneous evacuation of stone fragments. In the majority of clinical situations, however, the surgeon is faced with the task of removing several stone fragments in a separate process. Fortunately, there are a number of devices (both rigid and flexible) created specifically for this purpose, including graspers, baskets, and stone cones. We have found that in most situations a zero-tip basket facilitates stone removal with the lowest risk of collecting system injury. During PCNL, however, the larger nephroscope facilitates the use of rigid graspers.

In this chapter we will provide an assessment of the different lithotripsy devices currently clinically available.

Electrohydraulic lithotripsy

In 1955 Yutkin, an engineer at the University of Kiev, invented EHL, [2]. The clinical use of this technology for intracorporeal lithotripsy was not reported until 1970 when Rouvalis reported the use of the Urat-1 EHL in 100 patients [3]. Its use was limited to bladder stones until 1985 when a 5F EHL probe was used in combination with a rigid ureteroscope to treat ureteral stones [4]. Since that time the development of smaller EHL probes has facilitated their use in flexible scopes.

The mechanism of action of the EHL probe is that of an underwater spark plug. The probe consists of two separate concentric electrodes of different voltage polarities. As current is applied, the resistance of the insulative gap eventually is overcome and a spark is produced. This spark in turn vaporizes the surrounding fluid, creating a cavitation bubble that expands and subsequently collapses [2] (Figure 24.2). A total of three shock waves are created through the process of rapid expansion, collapse, and rebound of the cavitation bubble [5]. Therefore, if the probe is held in direct contact with the stone, minimal water is vaporized and an inefficient shock wave is created. There are many electrohydraulic generators available and probe size is variable from 1.9F to 9F. Initially it was believed that optimal efficacy was achieved with EHL in a 1:6 normal saline solution. It was later determined, however, that EHL has equivalent efficacies in hypotonic and isotonic (normal saline) solutions [6].

The major disadvantage of EHL pertains to its narrow margin of safety. Unlike ESWL, the shock wave of EHL is not focused and the diameter of the cavitation bubble is dependent upon the energy settings used, with the propensity to expand to greater than 1.5 cm. Concern for collecting system injury led to several animal studies. In 1990 Bhatta *et al*. found that EHL was more likely than a pulsed dye laser to result in bladder perforation in a

rabbit model [7]. Similarly, in 1994 Piergiovanni *et al*. compared the effects of several lithotripsy devices on ureteral and bladder tissue in a pig model. These researchers demonstrated that EHL results in extensive tissue lesions secondary to heat [8].

In clinical practice, the development of smaller EHL probes has improved clinical safety, which has been extensively evaluated throughout the literature. Hofbauer *et al*. reported a perforation rate of 17.6% in a prospective study of 72 patients [9]. More recently, Basar *et al*. reported a 2.9% perforation rate in their experience treating 207 ureteral and renal stones with EHL [10]. Overall, ureteral perforation is noted to have a mean incidence of 8.5% [11].

In addition to safety concerns, another disadvantage of EHL is its propensity to propel fragments, as well as to create an ample number of fragments when large (>15 mm) stones are treated. In a series of 43 patients with a single ureteral stone proximal to the pelvic brim treated with EHL, 14% required subsequent ESWL to treat stones that had been inadvertently pushed into the renal pelvis [12].

Despite the concerns over safety and stone retropulsion, with experience EHL has been proven safe and effective. It is noteworthy that the smaller probes are flexible enough to allow their use with flexible ureteroscopes. In a series of 207 ureteral and renal stones treated with EHL, 90.3% were successfully fragmented with an 82.1% stone-free rate at 20 months follow-up [10]. Similarly Green and Lytton reported excellent fragmentation of 32 of 36 stones with the use of a 5F EHL probe [4]. Overall, the literature demonstrates a mean 90% fragmentation rate for ureteral stones treated with EHL [11].

In addition, EHL is the least costly method of intracorporeal lithotripsy. The generator's upfront cost is relatively small (US$12 000) and the probes cost approximately US$200 each, with an average of 1–1.3 probes used per case [13].

Technically, the EHL probe should be held approximately 1 mm from the stone to allow for maximal effect and at least 2–5 mm from the lens of the scope to prevent instrument damage [5]. The goal of treatment is to create fragments that can either be easily extracted or passed spontaneously. Attempts to create fragments smaller than 2 mm have a higher probability of mucosal injury.

Ultrasonic lithotripsy

The upper limit of sound audible to the human ear is generally regarded to be 20 kHz. Sound waves with a frequency above this threshold are referred to as ultrasound waves. The first attempted use of ultrasound waves to fragment urinary calculi was reported in 1953 by Mulvaney [14]. Since then the technology has progressed significantly and ultrasonic lithotripsy is now commonplace within clinical endourologic practice.

Ultrasound waves can be created through a number of different mediums. All currently available ultrasonic lithotriptors utilize a piezoelectric model (Figure 24.3) In these devices a current is applied, from a separate generator, to a piezoceramic plate that in turn is excited. The plate generates vibrational energy in the form of ultrasonic waves at a frequency between 23 and 25 kHz. This energy is transmitted through the hand piece to a solid or hollow probe that is placed in contact with the stone. The vibrations of the probe transmit the energy to the calculus, resulting in a drilling effect.

Ultrasonic probes are manufactured in a variety of sizes from 2.5F to 12F. The larger probes incorporate a hollow channel through which suction is applied [the smaller probes (2.5F) are solid in design and therefore, lack suction]. The presence of this channel gives these devices a major advantage in that small stone fragments (<2 mm) can be evacuated as lithotripsy is performed. When this advantage is combined with the probe's rigidity and the inherent limitations to irrigation flow during ureterorenoscopy, it is evident why ultrasonic lithotripsy has had its greatest success during PCNL.

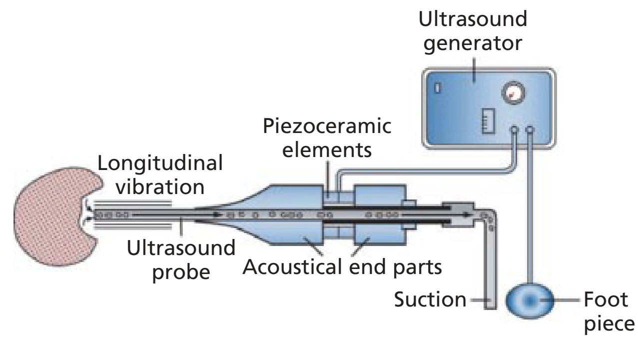

Figure 24.3 Mechanism of action of ultrasonic lithotripsy (adapted from Lingeman *et al*. [11], with permission).

As the mechanism of stone fragmentation in ultrasonic lithotripsy is purely mechanical, direct contact with the stone is necessary. As pressure is used to pin the calculus between the probe and urothelium in most cases, the question of safety and the potential for urothelial perforation is of utmost concern. When Piergiovanni *et al*. studied the effect of EHL, ultrasonic, pneumatic, and laser lithotripsy on pig bladder and ureteral tissues, it was found that perforation was not possible with ultrasonic or pneumatic lithotripsy. These animals were sacrificed on days 0, 1, and 6. After histologic examination it was demonstrated that injury was limited to abrasions of the epithelium [8]. These authors concluded that ultrasound and pneumatic lithotripsy are safer than EHL and laser lithotripsy. Howards *et al*. documented similar findings of minor epithelial changes in a canine model [15].

The mechanism of stone destruction raises a concern regarding the generation of heat at the site of interaction between the stone and probe. Although there is a potential for thermal injury, it is only of concern if irrigation is interrupted, as it has been demonstrated that at an irrigation rate of 30 mL/min the change in temperature at the probe tip is minimal (1.4°C) [16].

When researchers at Long Island Jewish Medical Center compared the efficiency of four different ultrasonic lithotriptors (Wolf, Olympus, Storz, ACMI) on a plaster of Paris stone phantom model, they demonstrated that the Wolf lithotriptor was the most efficient, while the Olympus was the least efficient with

incomplete fragmentation of the stone model [17]. Despite the intermanufacturer variability in efficiency, ultrasonic lithotripsy has been demonstrated to be an effective and safe means of lithotripsy.

As previously stated, a major limitation of the ultrasonic lithotriptor is its inherent rigidity. When used in conjunction with a semi-rigid ureterscope to treat ureteral calculi, a large working channel of at least 5F is needed to accommodate the smallest probe with an incorporated suction channel (4.5F). When this is not available, the solid 2.5F probe is utilized and no suction is possible. Despite these limitations, ureteroscopic success rates between 84% and 100% have been reported [18–22]. Given the rigid nature of the ultrasonic probes, which inherently limits the deflection of flexible scopes, ultrasonic lithotripsy of ureteral calculi may have its greatest utility in distal ureteral stones. This sentiment was documented in a study out of the UCLA Stone Center in which success rates of 91%, 94%, and 98% were reported in the proximal, middle, and distal ureter, respectively [23].

Ultrasonic lithotripsy has found its greatest utility in PCNL. The nephroscope's large caliber allows for the utilization of larger probes with a greater ability to evacuate stone fragments throughout the procedure. The first use of ultrasound to treat a staghorn calculus was reported in 1977 [24]. Since then many researchers have demonstrated percutaneous ultrasonic treatment of renal stones to be an effective and safe procedure with success rates of 80.4–100% [25–28].

Technically, when ultrasonic lithotripsy is applied, the stone should be trapped between the probe and the urothelium. Pressure is needed to maintain this relationship, but care should be taken to avoid excessive pressure as perforation is possible, especially in the thin-walled renal pelvis or ureter. Multiple short-duration applications of the ultrasonic energy to the stone results in fragmentation. Longer durations of activity provide shorter treatment times but carry the potential to generate a thermal injury and may lead to diminished vision. In addition to the aforementioned advantages of ultrasonic lithotripsy, it is relatively inexpensive. The generator costs approximately US$15 000 and there are no disposable components.

Pneumatic lithotripsy

Another example of a direct contact lithotriptor is ballistic lithotripsy. In this model of lithotripsy a projectile is set in motion, culminating in a jackhammer effect. Although any number of driving forces can initiate the movement of the projectile, the most notable and most widely utilized is compressed air. Using this model the Swiss Lithoclast has been found to be a very effective means of intracorporeal lithotripsy.

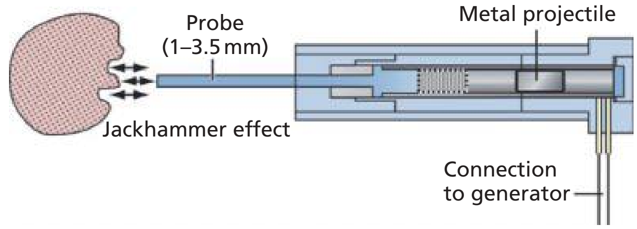

Figure 24.4 Mechanism of action of pneumatic lithotripsy (adapted from Lingeman *et al*. [11], with permission).

Developed in the early 1990s in Switzerland, the Swiss Lithoclast uses compressed air to propel a metal projectile against the head of a solid metal probe at a pressure of 3 atm and a rate of 12 Hz (Figure 24.4). Under close visual guidance, the tip of the metal probe is placed into direct contact with the calculus and repetitive impacts result in stone fragmentation. Since its first clinical use in 1991 [29], the Swiss Lithoclast has been extensively studied. Currently, probes are available in sizes ranging from 0.8 to 2.5 mm and a flexible nickel–titanium (nitinol) probe has been developed to facilitate its use in flexible endoscopy [30].

As in ultrasonic lithotripsy, the mechanism of action in pneumatic lithotripsy raises concern over the potential for collecting system injury, specifically perforation. As previously noted, when the effects of EHL, ultrasonic, pneumatic, and laser lithotripsy were evaluated on pig bladder and ureteral tissues it was determined that perforation did not occur with ultrasonic or pneumatic lithotripsy. On histologic examination, the lithoclast resulted in only partial abrasion of the epithelium and edema of deeper layers [8]. Additional animal studies have further documented the safety of the Swiss Lithoclast; notably Santa-Cruz *et al*. demonstrated no ureteral perforation following 6 min of continuous, direct contact activation in a pig model [31].

One of the limitations of pneumatic over ultrasonic lithotripsy is the solid design of the probe, and therefore the lack of a suction channel. The development of a suction channel through which pneumatic lithotripsy is commenced and suction is applied alleviated this concern. The Lithovac is available in several different widths (1.6, 3.5, and 4 mm) and lengths, and facilitates the evacuation of fragments less than 2 mm in size during lithotripsy. Fragments as large as 3.5 mm can be evacuated when the Lithoclast is removed from the channel [32]. In addition, the application of suction during pneumatic lithotripsy can counteract another major disadvantage of direct contact lithotripsy, retropulsion of stone fragments [33]. In the absence of suction, stone migration occurs in approximately 7.3% cases [11].

Pneumatic lithotripsy results in successful stone fragmentation in 73–100% of cases [9, 20, 33–37]. Its

successful utilization depends upon the ability to pin a calculus between the urothelium and the tip of the probe. This is understandably more difficult within the confines of the ureter and therefore the utility of pneumatic lithotripsy is best realized during cystolitholapaxy and PCNL, especially during the treatment of large stone burden or exceedingly hard stone compositions [38, 39]. The rigid nature of the probes also limits the ability to use the Swiss Lithoclast with ureteroscopy. To counteract these limitations, the flexible nitinol probe was manufactured. Despite the added ability to use the Lithoclast with a flexible ureteroscope, a significant decrease in tip displacement and velocity, and therefore effectiveness, is noted as the scope is deflected [40].

Technically, the use of pneumatic lithotripsy is facilitated by the use of a nondeflected working channel. Direct vision should always be employed to ensure safety as well as to facilitate adequate fixation of the calculus against the urothelium. In an *in vitro* biomodel the use of a larger probe (1.6 vs 0.8 mm) resulted in higher efficacy. When the smaller probe was used, however, a slower rate of impact (6 vs 12 Hz) was found to be more effective [41].

Pneumatic lithotripsy is somewhat more costly than EHL and ultrasonic lithotripsy as the generator costs approximately US$30 000, but there are no disposable components as each probe, costing US$150, is reusable.

Combined ultrasonic and pneumatic lithotripsy

Ultrasonic lithotripsy provides the surgeon with a very effective method for stone removal. The incorporated suction channel functions to decrease the effects of stone retropulsion and further assists with the removal of fragments less than 2 mm in diameter. Unfortunately, ultrasonic lithotripsy has limitations, especially when it comes to the destruction of very dense or hard stone compositions (calcium oxalate monohydrate).

Pneumatic lithotripsy has previously been demonstrated to be a very effective endoscopic lithotriptor, especially when treating hard or very large stones [38, 39]. Unfortunately, this device results in the formation of relatively large stone fragments and the lack of a suction channel further interferes with stone removal. As previously noted, a suction device for use with the pneumatic lithotriptor (Lithovac) has been developed but has failed to gain popularity due to its propensity to clog with stone debris [32, 33].

In an attempt to combine the benefits of these two technologies, the Lithoclast Ultra was developed. This device uses a combination of ultrasonic and pneumatic lithotripsy to accomplish calculus fragmentation and evacuation. A single control unit is activated via a foot pedal and enables the surgeon to use either of the lithotriptors individually or in combination. Suction is incorporated into the ultrasonic portion of the device.

The first clinical use of the combined lithotriptor was in 2001 by Haupt *et al*. [42]. Stone fragmentation was successful in all 15 patients with renal and bladder stones. Since that time a number of *in vitro* studies have examined the efficacy of the combined lithotriptor [43–46]. Auge *et al*. compared the combined lithotriptor to both standard pneumatic and ultrasonic lithotriptors in an *in vitro* study using a rigid 27F nephroscope and a phantom stone model [44]. The combination pneumatic/ultrasonic unit was found to be significantly more efficient in completely fragmenting and clearing the stone model compared to either pneumatic or ultrasonic lithotripsy alone (7.4 vs 23.8 vs 12.9 min, respectively). In addition, the study conducted by Hofmann *et al*. found that the combination unit was able to achieve fragmentation of five different artificial stones of defined hardness and density 25–200 times faster than pneumatic or ultrasonic lithotripsy alone [47].

The clinical utility of the combined lithotriptor has been evaluated in several studies [47–49]. In the largest of these studies, 68 patients were treated for staghorn calculi over a 2-year period. Overall stone-free rate, measured by postoperative kidneys, ureters, and bladder X-ray (KUB) and ultrasound, was 89.7%, with 23.5% requiring a second-look PCNL [47]. In an additional study by Pietrow *et al*., 20 patients with symptomatic renal stones were randomized to PCNL with either the combination lithotriptor or standard ultrasonic lithotripsy. The combination device required significantly less time for complete stone clearance (21.1 vs 43.7 min), as well as a greater rate of stone clearance (39.5 vs 16.8 mm^2/min) [48]. In yet another study, 30 patients were randomly assigned to PCNL with either a standard ultrasonic lithotriptor or the combined device. The stone-free rates were similar (46% and 66.7%, respectively, $P = .26$), however the combination of ultrasonic and pneumatic lithotripsy was more efficient for harder stones [49].

Combining the pneumatic lithotriptor's ability to successfully fragment hard stones with the disintegration and suction capabilities of ultrasonic lithotripsy helps to minimize stone retropulsion, facilitate stone clearance, and decrease operative times. Further studies are required to adequately define the role of the combined ultrasonic and pneumatic lithotriptor amongst the currently available intracorporeal lithotriptors. The available literature is, however, very promising.

Laser lithotripsy

Light amplification by stimulated emission of radiation (laser) is both a mnemonic as well as a descriptive

statement. Laser is a mechanism for emitting electromagnetic radiation through stimulated emission of photons. When an atom is stimulated by an external energy source, electrons become metastable and change their orbit. As this excited state decays, an emission of photons (light energy) occurs [50]. There are three differences between laser light and natural light: laser light is coherent (all photons are in phase), collimated (photons travel parallel to one another), and monochromatic (photons have the same wavelength) [50]. It is these characteristics that allow lasers to transmit high energy in a concentrated fashion.

The first functioning laser was constructed by Theodore H. Maiman in 1960 [51]. In 1966 Parsons was the first to use laser technology in urology when he experimented with the pulsed-ruby laser in canine bladders [52]. In 1968 laser technology was first utilized for lithotripsy [53]. The use of lasers was, however, limited by an excessive production of heat. The solution to the dilemma of thermal injury was the discovery of pulsed laser technology that resulted in high power density at the stone's surface with little heat dissipation [50].

Since the initial ruby laser, several lasers have been developed and implemented in intracorporeal lithotripsy. Lasers result in calculi fragmentation through several different mechanisms (see Figure 24.1). The neodynium:yttrium–aluminum–garnet (YAG) laser and Alexandrite laser function through a plasma-induced cavitation mechanism. Plasma, a gas in which a portion of the particles are ionized, is formed, and expands at the tip of the laser fiber. The rapid expansion and collapse of the resultant plasma bubble generates an acoustic shock wave that fragments the stone [54]. The holmium:YAG laser (HoL) is the only laser that is capable of fragmenting all compositions of calculi. It functions through a primary photothermal that results in stone vaporization [55, 56]. Despite the fact that the HoL is the most recently developed laser technology, it has become the most widely clinically utilized laser and is the laser on which our discussion will focus.

The holmium: YAG laser

The HoL is a solid-state laser operating at a wavelength of 2100 nm. Since its inception, HoL lithotripsy has been widely accepted as an intracorporeal lithotriptor. In fact, the most recent edition of *Campbell–Walsh Urology* states, "the holmium laser has become the mainstay of ureterorenoscopic lithotripsy" [11]. HoL fibers are available in diameters ranging from 200–1000 μm. Both the 200 μm and 365 μm fibers can be used with both semi-rigid and flexible ureteroscopes, and their flexible nature allows for preservation of flexion capabilities during ureteroscopy, a significant advantage.

The HoL is highly absorbed in water. Given that human tissues are chiefly composed of water, the energy of the HoL is absorbed superficially. In fact, the depth of tissue penetration has previously been proven to be 0.5–1.0 mm [31, 57]. This allows for safe use within the collecting system. In an *ex vivo* comparison of four different lithotriptors in a porcine ureteral model, the HoL was unable to induce perforation at a distance of 2 mm, even at very high power settings [31]. This is not to say that the HoL is unable to perforate the ureter. Several studies have found that both the EHL and HoL lithotriptors are more capable of ureteral perforation than ultrasonic and pneumatic lithotripsy. In one study, the HoL was reported to perforate the ureter after only 2 s of direct contact activation [8, 31].

Throughout the literature HoL lithotripsy has been demonstrated to be very effective, with success rates of 91–100% and stone-free rates after ureterorenoscopy of 87–100% [58–64]. Calculus location within the collecting system has been proven to affect HoL lithotripsy success. In a study of 598 stones treated with HoL lithotripsy, Sofer *et al*. evaluated patients at 6–12 weeks postoperatively and demonstrated an overall stone-free rate of 97%. When the procedures were stratified by stone location (renal, proximal ureter, middle ureter, and distal ureter), stone-free rates were 84%, 97%, 100%, and 98%, respectively [64].

The HoL is not solely used for retrograde approaches to calculi. HoL lithotripsy has been extensively used for PCNL, with success rates after a single session ranging from 61.4% to 89% [65–67]. When Malik *et al*. compared the HoL and pneumatic lithoclast in 60 patients undergoing PCNL of a single 2.5 cm stone, complication rates were similar as were the stone-free rates. Operative time, however, was significantly longer in the HoL group [68].

A group from China recently reported their experience with a novel approach to PCNL. Li *et al*. gained access to a posterior middle calyx via the 11th intercostal space and dilated their tract to 20F. The entire PCNL was then performed through this access with either an 8/9.8F semi-rigid ureteroscope or a 8.5/12.5F nephroscope. At the beginning of the procedure a 5–7F ureteral catheter was placed in a retrograde fashion to the level of the uteropelvic junction . This catheter was utilized to prevent stone migration, facilitate renal puncture, and for the instillation of forceful retrograde irrigant (normal saline) throughout the procedure. Either pneumatic or HoL lithotripsy was then employed through an average of 1.2 tracts per patient [69].

These authors reported their results from a total of 4760 minimally invasive PCNLs (MPCNLs) performed in 3610 kidneys, including 1240 staghorn calculi. An average of 1.3 procedures were performed on each kidney with an average operative time of 78 min.

Throughout the procedure stone fragments less than 0.3 cm were evacuated via the continuous instillation of irrigant through the indwelling ureteral catheter via a novel endoscopic pulsed perfusion pump. The authors utilized either a KUB or nephrostography postoperatively to assess for efficacy. At 48 h they achieved a stone-free rate of 89% with a significant complication rate of only 0.86% [69].

Li *et al*. concluded that their method of MPCNL provides a safer environment for percutaneous stone management with a lower risk of renal vessel injury. They note, however, that the long shaft of the instruments used can be quite cumbersome and a surgeon may require time to master the procedure [69].

The clear benefits of HoL lithotripsy include its ability to effectively fragment all stone compositions. In addition, the flexible nature of the laser fiber facilitates both flexible ureteroscopy and renoscopy (both antegrade and retrograde). The superficial penetration of the HoL laser provides it with a high margin of safety as long as care is taken to keep the fiber at least 1 mm from the urothelium. In addition, the lack of photoacoustic effects has resulted in the safe use of HoL lithotripsy in patients receiving anticoagulation therapy [70].

The disadvantages of HoL lithotripsy lie within its propensity to perforate the urothelium if activated within close proximity to the wall of the collecting system. In addition, the high initial cost of the HoL and its fibers is a deterrent to some institutions. The versatility of the HoL to treat multiple urologic diseases, including transitional cell carcinoma [71, 72], ureteral strictures [73–75], and benign prostatic hyperplasia [76–78], as well as nonurologic conditions [79, 80], however, helps to counteract the initial costs. As with other lithotriptors, stone retropulsion is also a concern in laser lithotripsy. In an *in vitro* model the 365 μm and 550 μm fibers were associated with the greatest degree of retropulsion, and the 200 μm fiber with the least [81]. Interestingly, HoL lithotripsy of uric acid stones produces cyanide gas. Despite the theoretical side effects of this, no significant cyanide toxicities have occurred as a result of HoL lithotripsy [82].

Technically, the HoL fiber should be kept at least 2 mm beyond the end of the endoscope to avoid damage to the lens system. We consider a systematic painting motion to represent the ideal use of the HoL. This process of lithotripsy allows for vaporization of the stone and avoids the formation of large fragments. When performing HoL lithotripsy it is important to remain vigilant in monitoring stone position to avoid ureteral injury. Care should be taken not to tunnel through a calculus as perforation through the opposite side may result in urothelial injury. In addition, care should be taken to avoid wires, baskets, etc. during laser lithotripsy as the HoL is capable of cutting through metal [83].

Conclusions

The most important determinant of which intracorporeal lithotriptor will prove most useful remains the specifics of the clinical situation. When treating stones in a retrograde fashion, i.e. ureterorenoscopy, the flexibility of the EHL and HoL lithotriptors may prove most beneficial. The HoL, in particular, has proven to be an extraordinarily versatile weapon within our arsenal of treatment modalities for urolithiasis.

When the larger stone burdens are encountered during PCNL, the mechanical lithotriptors, i.e. ultrasonic, pneumatic, and combination lithotriptors, may prove to be a superior choice. Their efficiency allows an experienced surgeon to treat large stone burdens with optimal operative times and low complication rates.

At our institution we consider a complete PCNL to be one in which both rigid and flexible renoscopy are employed to truly render the patient as stone free as clinically possible. We have found the combination of ultrasonic and pneumatic lithotripsy to be superior and therefore we employ the Lithoclast Ultra. Once the largest stone burden has been adequately eliminated, the rigid renoscope is exchanged for a flexible cystoscope through which the HoL is utilized to fully evaluate all calyces and fragment any residual stone fragments. Using this algorithm, patients have the greatest chance of being rendered stone free on follow-up imaging.

CHAPTER 25 Percutaneous Treatment of Calyceal Diverticula, Infundibular Stenosis, and Simple Renal Cysts

Amy E. Krambeck[1] & James E. Lingeman[2]

[1]Mayo Clinic Department of Urology, Rochester, MN, USA
[2]Methodist Hospital Institute for Kidney Stone Disease, Indianapolis, IN, USA

Introduction

Since its introduction in 1976, percutaneous nephrolithotomy (PCNL) has become an accepted treatment for urolithiasis [1]. Within one decade, PCNL evolved from a highly skilled undertaking performed by a handful of surgeons to a routine procedure performed by most urologists. Current indications for PCNL are large stone burdens, lower pole calculi, cystine stone disease, abnormal renal anatomy, and stones not amenable to ureteroscopy (URS) or shock-wave lithotripsy (SWL) [2]. Certain advantages of PCNL have been noted over open nephrolithotomy and SWL, including superior stone clearance, limited convalescence, and cost-effectiveness [3]. Although major complications are possible, analysis has demonstrated overall safety and effectiveness of this technique for complex calculi [4]. When complications occur at the time of PCNL they are often a result of obtaining percutaneous access, but can also result from the technique of stone removal and include hemorrhage, arteriovenous fistula, sepsis, hydrothorax, colocutaneous fistula, injury to surrounding viscera, ureteral avulsion, hypothermia, volume overload, electrolyte imbalance, myocardial infarction, pulmonary embolism, and death [5–7]. Notwithstanding the potential immediate complications, PCNL is considered to be without major long-term effects [8].

Due to the low complication profile and patient morbidity the limits of percutaneous surgery have been expanded from the realm of stone disease to the treatment of not only other benign conditions, but also renal malignancy. Furthermore, with advancements in imaging, surgical equipment, and technique, the success rate of percutaneous surgery has improved without compromising patient safety.

In this chapter we will review the role of percutaneous surgery in the treatment of three benign conditions: calyceal diverticula, infundibular stenosis with hydrocalyx, and renal cyst disease.

Calyceal diverticula

A calyceal diverticulum is a congenital smooth walled, nonsecretory urothelium-lined cavity within the renal parenchyma that communicates with the calyceal fornix through a diverticular neck. Urine is received by the diverticulum through passive retrograde filling from the adjacent collecting system, which can include the renal pelvis. Failure of small ureteral buds to degenerate is thought to be the origin of the diverticular variation. Calyceal diverticula are uncommon and have been noted in 0.21–0.6% of patients undergoing renal imaging [9–12], with bilateral occurrences observed in only 3% of patients with diverticula [13]. Calculi occur in 9.5–50% of diverticula. Although many of these cavities are asymptomatic, they can be associated with pain, hematuria, recurrent urinary tract infections (UTIs), and even damage to surrounding parenchyma [10, 12, 14, 15]. Furthermore, complete obstruction of the diverticular neck can be associated with sepsis, abscess formation, or hypertension [16].

The etiology of calyceal diverticular calculi is controversial, with both urinary stasis and underlying metabolic abnormalities implicated as factors [17–20]. It has

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

been suggested that particle retention secondary to urinary stasis, especially in the setting of a diverticulum, could be the cause of stone formation [20]. Liatsikos *et al*. further suggested stasis as a cause of diverticular calculi formation as they noted a low incidence of metabolic abnormalities in their cohort (25% in the calyceal diverticulum cohort vs 77.3% in other stone formers) [18]. However, other studies have noted metabolic derangements in 50–100% of patients with diverticular stone disease [17, 21]. More recently, both metabolic and stasis factors have been implicated [19]. Matlaga *et al*. compared the 24-h urine studies of 29 patients with calyceal diverticula to 245 calcium oxalate stone formers and 162 normal patients. They found that the urinary stone risk parameters of patients with calyceal diverticular stones were similar to those of the calcium oxalate stone-forming group. Furthermore, when compared to the normal cohort, the calyceal diverticular and calcium oxalate stone formers were significantly more hypercalciuric and their urine was significantly more supersaturated with calcium oxalate. Interestingly, the urine aspirated from the diverticulum of three patients in Matlaga *et al*.'s series demonstrated a significantly lower supersaturate of calcium oxalate compared to urine obtained from the renal pelvis of the same patient. The authors hypothesized that although these patients have baseline metabolic derangements, the urinary stasis in the diverticulum allows for incorporation of ions into a stone nidus, thus propagating stone formation and lowering local calcium oxalate supersaturation.

Diagnosis

The differential diagnosis for a calyceal diverticulum includes renal cyst, malignancy, solitary abscess, and most commonly hydrocalycosis secondary to infundibular stenosis. In geographic locations where tuberculosis is prevalent, the differential diagnosis of cortical cavitation secondary to renal tuberculosis should be considered, as the radiologic appearances of these two conditions may be similar [16]. Those patients who have an incidentally discovered asymptomatic calyceal diverticulum do not require treatment. However, for patients presenting with pain, recurrent UTI, hematuria, symptomatic calculi, or progressive renal damage, treatment should be undertaken.

The work-up for a calculus in a calyceal diverticulum includes urinalysis, complete blood count, basic metabolic panel, and imaging of the abdomen. The urine study should include both microscopy and a urine dipstick test for leukocytes, erythrocytes, protein, nitrites, and pH.

Initial imaging studies depend on the physician's practice preference and can be a renal ultrasound, plain abdominal X-ray [kidneys, ureters, and bladder (KUB)], or noncontrast computed tomography (CT) scan. Renal ultrasound will accurately diagnose a calyceal diverticulum in 80% of cases [22], with the classic ultrasound finding of milk of calcium [23]. When echogenic material is present in the affected kidney, the patient is scanned in different positions to demonstrate gravitational changes of the content, which is diagnostic of a calyceal diverticulum. KUB can also diagnose a calyceal diverticulum if milk of calcium is present. The milk of calcium will appear as a meniscus-like, half-moon-shaped calcification. Calyceal diverticula are often easily identified on noncontrast CT as a dilated outpouching from the collecting system containing a stone.

Once the diagnosis of a calyceal diverticulum is suspected, imaging of the collecting system should be performed to assess location of the diverticulum and communication with other elements of the kidney. With an intravenous pyelogram (IVP) or CT urogram, most calyceal diverticula will opacify if they have significant communication with the collecting system. The opacification will occur later in the examination since the diverticulum is filled in a retrograde fashion from the calyx or renal pelvis and thus delayed images are necessary [24]. A retrograde pyelogram can be helpful in determining where the neck of the diverticulum is located (Figure 25.1). If the neck or infundibulum is obstructed, the diverticulum will not opacify. The presence of an obstructed infundibulum can dictate how access to the calyceal diverticulum is achieved.

Treatment

Patients with calyceal diverticula can present a treatment challenge. Historically, these patients were treated by open surgical closure of the infundibulum, marsupialization and fulguration of the diverticular cavity, or partial nephrectomy. With technologic advances, the treatment of calyceal diverticula has become less invasive. Current minimally invasive treatment for patients with symptomatic calyceal diverticula includes SWL [25–27], URS [28–31], PCNL [24, 24, 28, 32–38], and laparoscopy [39, 40–44].

SWL for the treatment of calyceal diverticula is controversial. Although at short-term follow-up SWL can provide symptomatic pain relief in 36–70% of patients, stone-free rates are low, ranging from 4% to 20% [25, 26]. Jones *et al*. have found that with longer observation, patients initially rendered symptom free with SWL will subsequently become symptomatic and require retreatment [25]. The highest stone-free rate reported for SWL of calyceal diverticular calculi remains suboptimal at 58% [27]. Thus, SWL is rarely considered as monotherapy for calyceal diverticula as most investigators agree that to prevent stone recurrence, eradication of the diverticulum should accompany stone removal, a goal that is rarely achieved with SWL [45, 46].

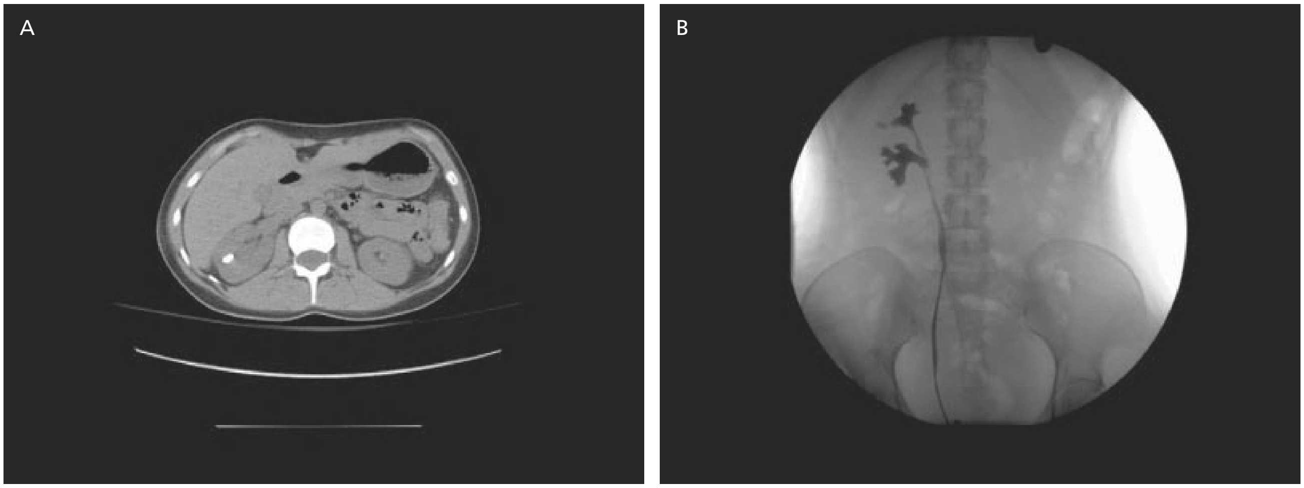

Figure 25.1 (A) Symptomatic calyceal diverticulum containing stone material in right kidney noted on CT scan of the abdomen and pelvis. (B) Retrograde pyelogram confirms location of the neck of the infundibulum to be originating from an upper pole calyx.

An advantage of URS over SWL is that while both are minimally invasive, URS allows for simultaneous ablation of the diverticular cavity. Retrograde URS is a reasonable option for certain patients with a diverticulum in the upper or middle portions of the kidney when the stone burden is small and the diverticular neck is short and easily accessible [45, 47]. Stone-free rates for URS range from 19% to 73%, but diverticular obliteration is as low as 18%; furthermore, a significant number of patients demonstrate residual symptoms and require retreatment [31, 32, 46]. Identification of the diverticular neck can be difficult with a retrograde approach and may account for the lengthy operative times (1.25–4 h) reported in some URS series [31, 47]. Furthermore, multiple treatments can be necessary to render the patient stone free and to completely ablate the cavity.

Laparoscopic management of calyceal diverticula has been described, but the indications for such an approach are limited. It has been suggested that anterior diverticula, especially if there is a thin layer of parenchyma overlying a large cavity, are suitable for laparoscopy [39, 40]. However, the laparoscopic approach is more invasive than PCNL with lengthy operative times (up to 2.5 h) even in experienced hands [40], thus limiting its widespread application. In general, laparoscopic management is reserved for diverticula that are large and extremely anterior or in ectopic kidneys where a percutaneous approach will be hampered.

Percutaneous treatment of calyceal diverticular calculi achieves high stone-free (87.5–100%) and obliteration rates of the diverticular cavity (76–100%) [24, 25, 33, 34, 36–38]. Over 90% of patients report symptomatic relief with percutaneous treatment [25, 28, 33–36] and long-term studies have demonstrated these results to be durable [36]. In most cases percutaneous access is directly into the calyceal diverticulum to allow use of a rigid nephroscope [45]. Direct puncture can be difficult if the cavity is small or if the calyceal diverticulum is located in the upper pole of the kidney. If direct puncture into the calyx fails, a neighboring calyx can be punctured and the diverticulum entered indirectly by perforating the wall of the diverticulum or by entering in a retrograde fashion, through the diverticular neck [48]. However, the indirect access technique is associated with inferior results and thus should be reserved as a secondary measure [49].

Biplanar fluoroscopy is the imaging modality most commonly used for percutaneous access when subsequent PCNL is planned [50]; this technique requires a radio-opaque target to aim at. Kim *et al*. have described a single-stage technique where percutaneous access is directed straight onto the stone [38]. If the targeted diverticular calculi are not visible with fluoroscopic imaging, contrast can be instilled into the diverticular cavity via a ureteral catheter placed in a retrograde fashion [36]. However, if the diverticular communication with the intrarenal collecting system is attenuated, the diverticulum may not readily fill with contrast. In such circumstances, ultrasound guidance can be utilized [51]. Unfortunately, it is difficult to monitor the guidewire manipulation with ultrasound imaging. Matlaga *et al*. have described CT- or ultrasound-guided pre-PCNL opacification of the calyceal diverticulum as an alternative approach [24]. Opacification of the diverticulum by interventional radiology provides the necessary target for percutaneous access in the operating room.

Once access is obtained into the diverticular cavity, stone removal is performed. It is imperative the patient

is rendered stone free. Kim *et al*. noted successful obliteration of the diverticular cavity was closely associated with rendering the patient stone free, and that successful obliteration of diverticula ranging from 5 to 44 mm in diameter was possible when the cavity was completely cleared of stone material; however, residual fragments increased the risk of incomplete diverticular resolution [38]. After all stone material is extracted, the urothelium should be inspected in an effort to identify a flattened renal papilla, the presence of which indicates an obstructed hydrocalyx rather than a calyceal diverticulum.

Once the cavity is confirmed to be a true diverticulum, treatment can include creating a large communication to the collecting system to promote drainage and prevent urinary stasis. When the infundibular connection to the renal collecting system can be found, dilation of this communication can be performed and the area stented with a nephrostomy tube [25, 34, 37]. If the infundibular connection cannot be found or traversed with a wire, some have advocated creation of a neoinfundibulum into the calyx or the renal pelvis [32, 35]. Both techniques require the placement of a nephrostomy tube for a prolonged period to ensure the channel will remain open. Furthermore, dilation of the infundibulum and creation of a neoinfundibulum have the potential to create significant bleeding. Neoinfundibulotomy should not be performed when the diverticulum is located anteriorly and normal parenchyma is traversed and dilated to form a connection to the collecting system [35].

Another treatment strategy is to fulgurate the diverticulum. Although the need for cavity ablation or destruction is a controversial issue [31], since the calyceal diverticulum is lined by a nonsecretory endothelium, most authors advocate fulguration at the time of PCNL [45]. Hulbert *et al*., however, suggested that trauma to the wall of the diverticulum caused by the percutaneous dilation process is sufficient to ablate the diverticular lumen [33]. Conversely, others have reported that dilation or incision of the diverticular neck without fulguration results in complete ablation of the diverticulum in only 30% of cases [52], as opposed to the 76–100% ablation rate when fulguration is performed [25, 34, 36, 53]. If fulguration is to be performed, the infundibulum of the diverticulum should not be dilated to maximize the chance of diverticular obliteration. Diverticular fulguration can be performed with [36] or without [38] ureteral catheterization utilizing a direct percutaneous access technique. Monga et *al*. performed fulguration of the calyceal diverticulum lining without any attempt at cannulation of the infundibular communication [36]. All patients were left with a ureteral stent for 2–4 weeks and the nephrostomy tube was removed at 24–48 h. The authors reported a 100% diverticular ablation rate and all patients were symptom free at 38 months follow-up. Kim *et al*. also presented their series of percutaneous diverticular ablation without identification of the infundibulum; however, ureteral catheters were not placed in this series and 20 of 21 patients were sent home tubeless on postoperative day 1 [38]. Operative times for this series were less than 60 min. At 3-months follow-up, all diverticula had decreased in size and 87.5% had completely resolved.

Technique

If retrograde instillation of contrast is not necessary because the diverticulum is easily identified from its stone contents, a single-stage procedure is performed. In a single-stage PCNL technique, patients are placed in the prone position without an external ureteral catheter. A C-arm is used to visualize the diverticular calculi. When possible a direct infracostal puncture is performed using an 18G diamond-tipped needle and a biplanar fluoroscopic triangulation technique [45]. When access is achieved, a 0.035-inch J-tipped movable core guidewire is coiled inside the diverticular cavity, taking care to avoid wall perforation with the stiffer portion of the wire. The main advantage of the movable core J-wire is that the flexible distal end of the wire can be adapted to the size of the diverticulum, while the wire proximal to the moved core remains stiff enough to function as the working wire. With the J-wire in place, an 8/10F coaxial dilator is passed over the J-wire in a sequential fashion. The 8F dilator is removed and a second 0.035-inch J-tipped movable core wire is coiled inside the diverticulum and used as the safety wire. The tract is balloon dilated over the working wire. Special attention is given to the placement of the balloon dilator and the wires to prevent any trauma to or perforation of the back wall of the diverticulum. A 30F Amplatz sheath is then passed over the balloon dilator under fluoroscopic guidance. The balloon dilator has a taper on the distal end that precludes placement of the sheath directly into the diverticular space unless the diverticulum is large. Next, an offset 24F rigid nephroscope is placed inside the access sheath using normal saline irrigant. An 11F alligator forceps is used to manually dilate the part of the tract immediately adjacent to the diverticulum, allowing for advancement of the scope and subsequently the sheath into the diverticular lumen (see Video 25.1).

Once the offset nephroscope is gently guided into the diverticular cavity, ultrasonic lithotripsy or grasping forceps are used to remove the stone burden. After removal of all stone material and confirmation that a renal papillae is not present, the irrigant is switched to 1.5% glycine and a resectoscope with a rollerball electrode is used to fulgurate the diverticular lining (see Video 25.2). The infundibular communication is neither assessed nor dilated. An 18F red rubber catheter or an

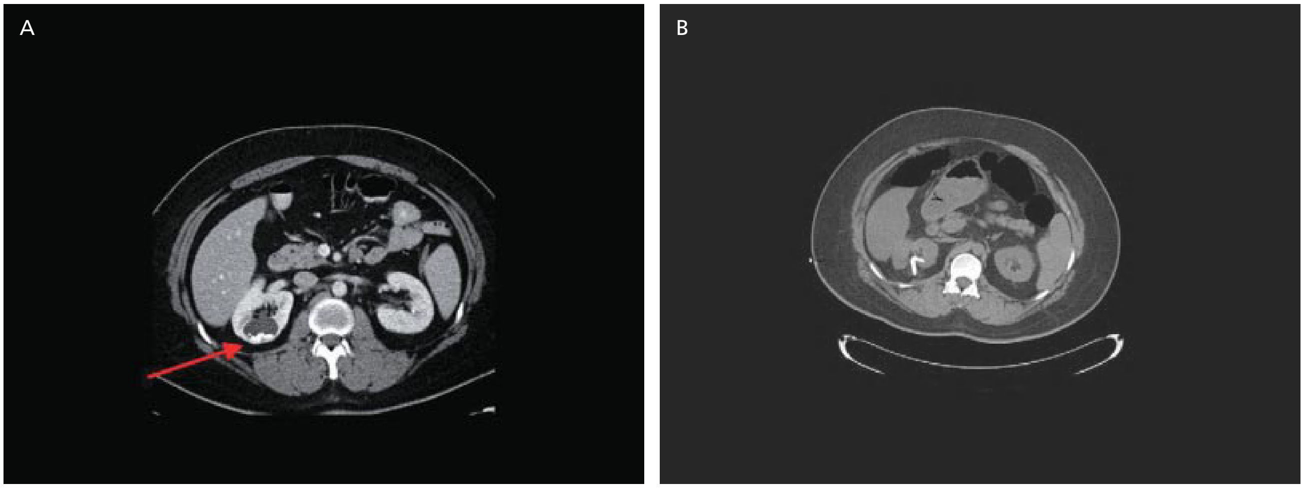

Figure 25.2 (A) Large calyceal diverticulum located in the right kidney containing stone debris (arrow). (B) Post percutaneous removal of stone and ablation of the cavity; note the 10F Cope loop nephrostomy tube in place.

8.5F Cope loop catheter is placed in the cavity at the conclusion of the procedure (Figure 25.2). The Cope loop is only used for calyceal diverticula that are large enough to house the entire loop. Proper placement of the nephrostomy tube is confirmed by contrast instillation under fluoroscopy. If the diverticulum is small, the red rubber catheter acts as a perinephric drain, as it usually becomes dislodged from the diverticular cavity.

For patients in whom the stone cannot be visualized fluoroscopically, either because it is too small or is radiolucent, the direct puncture technique cannot be performed unless the diverticulum is first opacified. In such cases, a retrograde pyelogram is first performed via a ureteral catheter. If the diverticulum does not readily opacify due to a narrow infundibulum, percutaneous opacification with either CT or ultrasound guidance is performed. The patient is transported to the radiology suite, CT or ultrasound is used to identify the diverticulum and, a puncture site overlying the posterior aspect of the kidney is selected. Local anesthesia is injected and a 20G spinal needle is manipulated under radiographic guidance into the calyceal diverticulum. Iodinated contrast is gently instilled until resistance is encountered, and KUB imaging is performed to confirm opacification of the diverticulum. Care must be taken not to inadvertently overfill the diverticular cavity by instilling contrast under too great a pressure, as extravasation may occur, making subsequent fluoroscopic targeting difficult. The patient is then transported directly to the operating room. Renal access and PCNL are performed as outlined above. It is imperative that little time elapses from the injection of contrast to the initiation of the procedure as too long a delay may permit the absorption of the contrast and the loss of the target.

Potential complications

The general complications associated with percutaneous access apply to percutaneous treatment of calyceal diverticula: hemorrhage, retroperitoneal extravasation, pneumothorax, hemothorax, and adjacent organ injury (see Chapters 30–32). However, some unique complications bear special mention. If ablation of the diverticular cavity is to be performed without infundibular dilation, it is imperative that infundibular stenosis is ruled out by lack of papillae visualization. If infundibular stenosis is misdiagnosed as a calyceal diverticulum and fulguration of a dilated calyx with functioning papillae is performed, urinoma with fistula formation can occur. Since only a targeted stone is generally treated in the case of a calyceal diverticulum, we generally make every effort to place our access site infracostal, thus substantially decreasing the risk of pleural injury and subsequent hydrothorax. Another unique theoretical complication is hyponatremia. Ablation of the calyceal diverticular cavity should be performed quickly. If the access sheath is not properly positioned or an extensive amount of time is spent ablating the cavity, absorption of the water irrigant necessary for cauterization can potentially occur.

In most instances it is not possible to pass a guidewire into the main renal collecting system from the diverticulum. With the access wire only coiled in the diverticulum, loss of access is a realistic complication. If serial dilation is performed, a false passage can be created through repetitive insertion and removal of dilators over a poorly secured access wire. If balloon dilation is performed, care must be taken not to advance the dilator too far into the diverticulum and cause posterior wall perforation leading to hemorrhage. For small

diverticula, we suggest just placing the tip of the balloon dilator into the diverticulum so that the access sheath is just outside the diverticulum. The remainder of the tract is then manually dilated under direct vision using grasping forceps. Once the scope is securely inside the diverticulum, the access sheath can then be advanced over the nephroscope.

Outcomes

Percutaneous treatment of calyceal diverticular calculi achieves a stone-free rate ranging from 87.5% to 100% and cavity obliteration rates of 76–100% [24, 25, 33, 34, 36–38]. Recently, two techniques for the treatment of calyceal diverticula were recently compared: an older technique where the communication between the diverticulum and the collecting system is identified and dilated, and a newer technique where the cavity is just ablated [54]. The old technique was utilized in 28 patients and the new technique of diverticular fulguration in 57 patients. The age and gender distribution of both cohorts was similar. Of the 45 patients with location of the diverticula documented, 21 (46.7%) were upper pole, 18 (40%) mid pole, and six (13.3%) lower pole. Mean diverticular diameter was 15.8 mm (range 5–44 mm). Mean operative time was longer for the old technique cohort at 96.4 min (range 30–210 min) compared to 67.3 min (30–150 min) in the new treatment group. This difference was attributed to the new technique not requiring cystoscopy and external stent placement. A postoperative noncontrast CT scan was performed on 74 (87.1%) patients, and of these 66 (89.2%) were stone free after the initial procedure. Compared to the old technique, the new technique had a higher initial stone-free rate (94.2% vs 77.3%). Overall, final stone-free rate after primary and secondary PCNL for the entire cohort was 97.5% (78 of 80). Mean length of hospitalization was longer in the old technique cohort compared to the new (2.32 vs 1.12 days). Postoperative complications occurred in eight patients (9.4%). Overall, blood transfusions were required in three patients and two patients experienced a pulmonary complication.

There were 26 real units with the new ablation technique that had follow-up IVP at 3 months. The diverticulum was only visible on follow-up imaging in seven patients, and in four of these a decrease in size was noted, while there was no comment on size by the radiologist in the other three. Over the follow-up period, no patients experienced recurrent stone events in the area of the calyceal diverticulum. In summary, when the old infundibular dilation technique was compared to the new percutaneous diverticulum dilation technique, we noted a shorter hospitalization time and higher stone-free status with with the latter.

Post-treatment evaluation

All retrieved stone material should be sent for stone analysis to assess stone composition. Abdominal imaging should be obtained to assess stone-free status after surgical intervention. We prefer a noncontrast CT scan on postoperative day 1 prior to removal of the nephrostomy tube. To assess resolution of the calyceal diverticulum imaging of the collecting system should be performed at 3 months postoperatively either with an IVP or CT urogram.

Metabolic evaluation should also be performed 4–6 weeks after surgery or prior to surgical intervention. The current literature supports metabolic evaluation for patients with calculi containing calyceal diverticula. All patients with a calyceal diverticulum evaluated in one study had at least one metabolic abnormality, including hypercalciuria, hyperuricosuria, hypocitraturia, and hyperoxaluria [21]. The most common abnormality noted was low urine volume. Matlaga *et al*. noted that patients with calyceal diverticula had similar stone risk parameters as a cohort of patients with calcium oxalate stones without calyceal diverticula [24]. Both the calyceal diverticula and the calcium oxalate stone cohorts had significantly higher stone risk parameters when compared to a group of normal patients. Based on these studies, we perform metabolic evaluation for all patients treated for a symptomatic calyceal diverticulum.

Infundibular stenosis

Infundibular stenosis is defined by a dilated calyx with or without stone, draining through a narrowed infundibulum into a nondistended renal pelvis. It can be caused by extrinsic compression by malignancy or retroperitoneal fibrosis. Infundibular stenosis can also be caused by intrinsic narrowing from tuberculosis, chronic stones, infection, or scarring secondary to iatrogenic injury [55]. A rare cause of infundibular stenosis is a crossing segmental artery, which generally affects an upper pole calyx and is known as Fraley's syndrome [56]. Occasionally, an infundibular stenosis will be so severe that the infundibulum becomes completely occluded and there is no communication between the calyx and renal pelvis, which is termed an excluded calyx. Since the infundibular stenosis is so rarely encountered, the true incidence of the disorder is unknown.

Genitourinary tuberculosis (TB), although rare, deserves special discussion as it is the most common cause of infection-induced infundibular stenosis. Most patients with infundibular stenosis secondary to TB are asymptomatic, but they can present with microhematuria, painless frequency, recurrent cystitis, and the hallmark diagnostic sign of sterile pyuria [57]. Up to 20% of patients will present with renal calcifications and focal

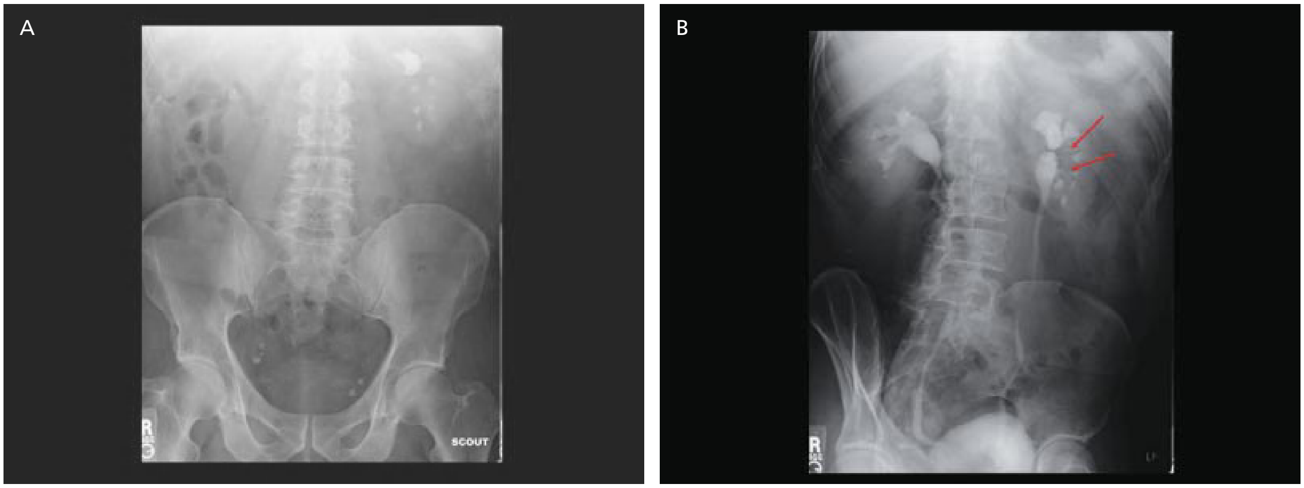

Figure 25.3 (A) Plain abdominal X-ray of the abdomen and pelvis demonstrating multiple calyceal stones in the left kidney. (B) Excretory urogram demonstrates stenosis of multiple infundibuli leading to the stone-containing calyces (arrows).

TB involvement [58]. Approximately 90% of patients with renal TB will have a positive tuberculin skin test, denoting prior inhalation exposure, but not active disease. Definitive diagnosis is made with serial, at least three, early morning urine collections for acid-fast smear and culture. Polymerase chain reaction tests can also be used and are highly sensitive and specific, with results available within hours as opposed to the weeks necessary for culture results. Once the diagnosis of infundibular stenosis secondary to TB is made, initial management with anti-TB chemotherapy should be performed. If the stenosis does not respond after 4–6 weeks of appropriate chemotherapy and remains symptomatic, then surgical intervention should be instituted. Dilation of the stenosis is rarely successful and therefore partial nephrectomy versus complete nephrectomy should be considered [57, 58].

Diagnosis

Similar to calyceal diverticulum, infundibular stenosis can be entirely asymptomatic and in many instances is discovered incidentally. Acquired infundibular stenosis, although generally asymptomatic, has been reported to lead to progressive renal failure, and some physicians advocate surgical correction [59]. Symptomatic patients with infundibular stenosis most commonly present with flank pain. Other presenting symptoms include hematuria and recurrent UTIs [55]. Stone material may or may not be present in the hydrocalyx giving rise to the above symptoms. The differential diagnosis of infundibular stenosis includes calyceal diverticulum and renal cyst.

The diagnosis of infundibular stenosis is suggested radiographically, but can only truly be made by endoscopic visualization of a papilla in the dilated hydrocalyx. With contrast imaging either via CT urogram or excretory urogram, infundibular stenosis is demonstrated by a dilated cystic outpouching of collecting system within the kidney that may or may not communicate with the renal pelvis (Figure 25.3). If the original imaging suggests the presence of a crossing segmental renal artery, an arteriogram or CT angiogram should be obtained before any endourologic surgical removal to prevent potential complications as formal surgical repair may be necessary [60, 61].

Treatment

The two indications to treat an infundibular stenosis are to relieve obstruction of the dilated calyx or to permit access to a retained stone within the calyx. There are four possible approaches to the treatment of infundibular stenosis: laparoscopic, retrograde ureteroscopic, percutaneous direct, and percutaneous indirect.

In general, hydrocalyx with functioning draining parenchyma should not be approached laparoscopically [62]. Wolf reported his experience with two cases of infundibular stenosis treated laparoscopically [62]. One case was misdiagnosed as a calyceal diverticulum and resulted in a postoperative urinoma; the other cases was successfully treated. Successful laparoscopic treatment requires proper technique and appropriate patient selection. The ideal candidate for laparoscopic treatment is a poorly functioning renal segment that is anteriorly located. If laparoscopic treatment of infundibular stenosis is performed, the renal parenchyma should be thoroughly fulgurated to ensure no functional tissue remains.

Ureteroscopic treatment of infundibular stenosis is also possible [61, 63] and its success relies on the use of

the holmium:YAG laser. If the infundibulum can be seen and cannulated with a wire ureteroscopically, it is then opened using the holmium laser. If bleeding is minimal, then the infundibulum is further dilated using a balloon over the wire previously placed fluoroscopically. The dilated infundibulum is then stented for 4–6 weeks to allow adequate healing. Most reports on ureteroscopic treatment have been limited to case studies and long-term follow-up is lacking; however, for appropriately selected patients, it is an appropriate treatment alternative.

Percutaneous treatment can be performed with direct puncture into the hydrocalyx or through indirect puncture into an adjacent calyx. Either technique is acceptable. Determination of which technique to use is based on the location of the affected calyx and adjacent anatomy. In general, the approach for treating infundibular stenosis through the direct approach is very similar to that for the treatment of a calyceal diverticulum. A retrograde ureteral catheter is placed to opacify the collecting system and the hydrocalyx. If the calyx is completely excluded and no stone material is present to aim for fluoroscopically, then ultrasound- or CT-guided access is necessary if a direct approach is to be utilized.

Technique

Percutaneous access to the affected renal segment is obtained using a similar technique to that already described for a calyceal diverticulum. Retrograde instillation of contrast outlines the calyx in question. After the hydrocalyx is accessed, if the initial guidewire does not easily cross the infundibulum into the main collecting system, then the wire is coiled in the hydrocalyx in a similar fashion to a calyceal diverticulum. Once the access sheath is positioned in the calyx after balloon dilation of the percutaneous tract, the calyx is inspected with a rigid or flexible nephroscope to identify the papilla and the infundibulum. If the infundibulum is not easily identified, then retrograde instillation of methylene blue or indigo carmine via the external ureteral catheter may be helpful. In the case of an excluded calyx where an infundibulum will not be identified, some authors advocate the retrograde advancement of a wire through the external ureteral catheter fluoroscopically while the surgeon observes the calyx through the nephroscope [55]. Movement produced by the wire allows for identification of the main collecting system and may permit successful cut down through the stenosed segment to the wire.

Once the infundibulum is identified, a hydrophilic wire is advanced across it into the main collecting system. The infundibulum can then either be balloon (6 mm × 4 cm) dilated or incised with a holmium laser or cold knife. If incision is to be performed, the area should be inspected for any obvious underlying pulsations and then cuts made at the superior and inferior aspects to limit blood loss [64, 65]. A single deep cut is to be avoided as this may result in unnecessary bleeding. Incision can then be augmented with balloon dilation performed under fluoroscopic guidance.

After dilation of the infundibulum, the hydrocalyx should be drained. Placement of a ureteral stent across the dilated infundibulum, with proximal coil in the hydrocalyx and distal coil in the bladder, is one option. A standard double-J stent can be used. Others have suggested that placement of two standard stents is optimal [64]. If placement of a stent is to be performed, we prefer an endopyelotomy stent with a larger proximal diameter and quick taper to a standard 7F distally. Another option for drainage is to place the nephrostomy tube across the infundibulum with coil in the renal pelvis. No study has demonstrated that eventual infundibular patency is affected by type, size, or duration of drainage [55]; thus mode of drainage should be dictated by surgeon and patient preference.

If an indirect approach is to be used, access is gained into a calyx adjacent to the hydrocalyx. Flexible nephroscopy is used to identify the stenosed infundibulum. The infundibulum is then balloon dilated or incised using the holmium laser in a manner very similar to the ureteroscopic approach. A ureteral stent is then placed across the narrow infundibulum with proximal coil in the hydrocalyx and distal coil in the ureter. If it is not technically possible to place a ureteral stent, a percutaneous nephrostomy tube is placed across the dilated infundibulum into the hydrocalyx.

Potential complications

Potential complications related to the percutaneous treatment of infundibular stenosis are similar to those found with treatment of a calyceal diverticulum, but additionally include bleeding and restenosis. All efforts to avoid pulsatile vessels should be made at the time of the procedure. Minor-to-moderate bleeding can be controlled with the laser or point coagulation if needed, but is rarely necessary. Most minor bleeding should be allowed to resolve spontaneously to limit the risk of scar formation that can occur with excessive energy deposition.

Outcomes

The true outcome for the treatment of infundibular stenosis is unknown, as most reports are limited to small case series and are mixed with patients with calyceal diverticulum. Of the reported series with limited follow-up, the success rate is low at 60–80% [55, 66–68]. However, the type of treatment (i.e. balloon dilation,

Category	Description	Malignancy risk
I	Simple, thin walled without septa, calcifications, or solid components.	<1%
	Does not enhance with contrast and measures as water density	No follow-up required
II	Thin walled cyst with a few thin (<1 mm) septa with or without fine calcifications. Uniformly high-attenuation (>20 HU) lesions of <3 cm with sharp margins that do not enhance	3%
IIF	Multiple thin septa. Septa are thicker than hairline or slightly thick walled. Calcifications may be nodular and thick without contrast enhancement. No enhancing soft tissue elements	5–10% Follow-up recommended
	Intrarenal nonenhancing high attenuation renal lesions of ≥3 cm	
III	Indeterminate cystic masses that have thickened irregular walls or septa that enhance.	40–60% Surgical excision recommended
	Thick irregular calcifications	
IV	Cystic soft tissue masses that enhance.	>80%
	Irregular margins/prominent nodules	Surgical excision recommended

incision alone, incision plus dilation, etc.), the cause of the infundibular stenosis (i.e. iatrogenic, vascular, infection, etc.), and time of follow-up must be considered. No treatment method has been evaluated extensively enough to lead to one surgical approach being recommended over another.

Post-treatment evaluation

Since infundibular stenosis is such a rare condition, currently no clear standardized follow-up protocol has been established. We recommend that the treated infundibulum be stented either with a ureteral stent or percutaneous nephrostomy tube for 4–6 weeks post intervention. Urine culture should be negative prior to stent removal. If the urine culture is positive for infection, an appropriate course of antibiotics should be administered prior to stent or nephrostomy tube removal. After stent or nephrostomy tube removal, we recommend repeat contrast imaging of the affected kidney with either an excretory urogram or CT urogram at 4–6 weeks. If there is no evidence of recurrent stenosis, then the patient should be followed with yearly ultrasound imaging.

Symptomatic renal cysts

Simple renal cysts are commonly encountered on routine abdominal imaging and are seen as noncommunicating fluid-filled structures arising from the renal parenchyma. The incidence of renal cysts increases with age such that by age 40 years 27% of adults have renal cysts and 61% by 80 years [69]. Cysts are more common in men than in women and can be associated with a genetic predisposition, as with adult polycystic kidney disease (APKD). The majority of cysts are clinically insignificant and do not require treatment [70]; despite the fact that they can increase in number and size over time. Should a cyst become symptomatic, it may do so secondary to compression of the renal collecting system or adjacent organs, infection, or bleeding. Patients with symptomatic renal cysts may present with hematuria, flank pain, or even fever if infected. An association between renal cyst disease and hypertension has also been made; however, the exact causal relationship is uncertain [71].

Diagnosis

In general, simple renal cysts are benign, but more complex cysts can harbor a significant risk of malignancy. The appearance of the cyst on CT, magnetic resonance imaging (MRI), or ultrasound can help predict the likelihood of underlying malignancy and can be scored using the Bosniak classification (Table 25.1). In general, the diagnosis of a cyst can be made confidently with ultrasound, MRI, or CT alone. If there is concern for an infected cyst, it should percutaneously aspirated and the fluid sent for culture. An excretory urogram or CT urogram may be helpful if compression of the underlying collecting system is suspected. The differential diagnosis for a renal cyst includes calyceal diverticulum, hydrocalyx, ureteropelvic junction obstruction (UPJO), and cystic renal mass.

Treatment

Multiple options exist for the treatment of symptomatic simple renal cysts, including percutaneous puncture/aspiration with sclerotherapy, retrograde ureteroscopic

puncture, laparoscopic or open unroofing, and percutaneous resection. Initially, open cyst decortication or even nephrectomy was the preferred treatment of symptomatic cysts. Due to the morbidity associated with the open surgical approach to simple renal cysts, percutaneous aspiration with injection of a sclerosing agent (alcohol, quinacrine, glucose, iophendylate, bismuth phosphate, or phenol) became a minimally invasive treatment alternative [72]. Although short-term results report a 75–100% satisfactory outcome with percutaneous aspiration and sclerotherapy, long-term data greater than 5 years are lacking [55]. The role of percutaneous aspiration and sclerotherapy has been further limited by reports of significant complications, including UPJO, cyst abscess, fever, pain, and recurrence [73, 74].

There have been reports of retrograde treatment of renal cysts via ureteroscopy but these are limited [75]. The ureteroscopic approach is the least invasive, but is limited to small cysts adjacent to the collecting system. With the ureteroscopic approach, the urothelium separating the collecting system from the cyst is opened using a holmium laser, allowing for internal marsupialization. To avoid injury to the renal vessels, the cyst should not be too centrally located.

Laparoscopic unroofing is ideal for large anteriorly located simple renal cysts [76, 77]. One advantage of laparoscopic ablation is the ability to identify surrounding structures, such as the renal hilum or aberrant vessels. Despite these advantages the laparoscopic approach is more invasive than percutaneous procedures, requiring multiple port sites and potentially longer operative times [72].

Percutaneous resection and intrarenal marsupialization was reported in 1984 [78]. Multiple follow-up series have confirmed the efficacy and safety of the procedure [72, 79–81]; however, long-term outcomes are limited [81]. Our experience with percutaneous resection of renal cysts has lead us to consider the procedure for all symptomatic renal cysts that appear accessible percutaneously. This approach is especially attractive if there are concomitant renal stones requiring treatment.

Technique

The cyst can be accessed either using ultrasound guidance or fluoroscopic guidance. If fluoroscopic guidance is used, an external ureteral catheter is placed prior to prone positioning, to allow for retrograde installation of contrast. The area of the collecting system distorted by the renal cyst is considered the percutaneous target. Standard triangulation technique is then used to percutaneously access the cyst. The aspiration of fluid confirms intracyst positioning of the needle; the fluid should be sent for cytology and culture. Access to the cyst is then achieved in an identical fashion as for a calyceal diverticulum using a removable core 0.035-inch J wire coiled inside the lumen of the cyst. An 8/10F sequential dilator is used to place a second safety wire and a balloon dilating system is used to position the 30F access sheath into the lumen of the cyst.

If the cyst is not large enough to be percutaneously accessed directly, then indirect access can be utilized. Using the indirect access technique, a calyx adjacent to the cyst is accessed percutaneously in the standard fashion. The cyst is then approached from the collecting system, either by withdrawing the sheath from the collecting system and visually advancing it into the adjacent cyst, or using flexible nephroscopy and visualizing the cyst endoscopically from the collecting system. If flexible nephroscopy is utilized, the cyst is simply marsupialized into the collecting system using a holmium laser, as previously described for the ureteroscopic approach.

Regardless of access, once the sheath is inside the lumen of the cyst, the irrigation fluid is switched to 1.5% glycine. Using a rollerball electrode, the entire cyst wall is fulgurated. Electrocautery should be set at the lowest possible settings to allow for blanching of the cyst wall without perforation [72]. After fulguration a portion of the cyst wall is excised using grasping forceps or loop resection for marsupialization to the retroperitoneum. We do not routinely marsupialize to the collecting system, since reports indicate recurrence rates are not decreased with this procedure [72]. Once the procedure is completed, an 8 or 10F locking Cope loop nephrostomy tube is left inside the cavity overnight, with removal the next day. Another option for drainage is to place a red rubber catheter in the cyst overnight if the cavity is not large enough for the loop nephrostomy tube.

Potential complications

Potential complications of percutaneous resection of simple renal cysts are similar to those found with treatment of a calyceal diverticulum, but also include recurrence of cyst or incomplete obliteration with recurrence of symptoms.

Outcomes

Reports on percutaneous resection of simple renal cysts are limited. In a recent series by Kang *et al*., nine patients with symptomatic renal cysts were managed with percutaneous resection with a mean follow-up of 21 months (8–25 months) [72]. There were no complications reported in the series. Complete resolution of pain was noted in 89% of patients and complete obliteration of the cyst in seven patients (78%). Similar initial short-term results have been reported by Gelet *et al*. who found complete resolution of the cyst in 60% of patients

and only a 15% recurrence rate [80]. Hubner *et al*. initially reported a 57% cyst resolution rate and 7% recurrence rate at short-term follow-up [82]. However, when 10 of these patients were followed for a mean of 45.7 months (26–66 months), 50% of the cysts were detectable or near their pretreatment size [81]. Interestingly, none of the patients experienced recurrence of their original symptoms despite recurrence of the cyst.

Post-treatment evaluation

There are no standard follow-up recommendations for patients treated with percutaneous resection of a simple renal cyst. We recommend a renal ultrasound and urinalysis 3 months post procedure. The patient can then be followed up as needed for symptom recurrence.

Conclusions

Percutaneous treatment of calyceal diverticula, infundibular stenosis, and symptomatic simple renal cysts can be a safe, effective treatment alternative in appropriately selected patients. Although experience is limited with these percutaneous techniques, long-term data support the role of percutaneous treatment of calyceal diverticula as initial intervention. Even with limited data to support long-term success, the low complication profile for percutaneous treatment of hydrocalyx associated with infundibular stenosis and symptomatic renal cysts also supports its role as a first-line minimally invasive treatment option.

CHAPTER 26

Percutaneous Instillation of Chemolytic, Chemotherapeutic, and Antifungal Agents

Mohamed A. Elkoushy, Philippe D. Violette & Sero Andonian
Division of Urology, McGill University Health Center, Montreal, Quebec, Canada

Introduction

Percutaneous instillation of topical agents started in 1924 when Crowell disintegrated a cystine stone by instillation of alkaline solution into the kidney [1]. Before the advent of miniaturized fiberoptic flexible ureteroscopes and nephroscopes, the nephrostomy tube provided a conduit for direct instillation of topical agents into the collecting system, thus minimizing systemic side effects. Chemolytic agents for stones were the original and most common agents. Currently, two other categories of topical instillation agents are used; chemotherapeutic/immunotherapeutic agents as adjuvant treatment for upper tract transitional cell carcinoma (TCC), and antifungal agents.

An advantage of direct instillation when compared with systemic therapy is longer duration of direct contact of the topical agents with the collecting system, which allows topical agents to reach the target organ in appropriate concentrations. This leads to shorter therapy and avoidance of harmful systemic side effects [2]. In addition, these topical agents can be administered in patients with compromised renal function, inadequate urinary drainage, and high operative risk due to comorbidities [3]. However, it is important to note that there are several contraindications to initiating or continuing percutaneous instillation of topical agents. These include positive urine culture, febrile patient, persistent flank pain, extravasation of irrigation fluid, or intrapelvic pressure greater than 25 cmH_2O [4].

With recent advances in endourologic technology, indications for instillation of topical agents have evolved and can be very useful for select patients. Although principles of instillation of topical agents into the collecting system are simple, minor errors in technique can result in catastrophic complications. Therefore, in addition to the urologist, both the nursing staff and the patient should be aware of the tell-tale signs of complications and if they arise the treating physician should be informed and the instillation stopped immediately. Therefore, urologists should be familiar with techniques of instillation, indications and contraindications, success rates, and any potential side effects.

In this chapter, chemolytic agents (for stones), chemotherapeutic/immunotherapeutic agents for upper tract TCC, and antifungal agents will be reviewed.

Techniques of irrigation/instillation

Topical instillation of agents into the collecting system depends on the principle of free flow of the solution throughout the collecting system, thus providing a continuous milieu of irrigant solution to the stone, upper tract TCC, or fungal ball. This can be achieved through several techniques: either retrograde fashion, percutaneous antegrade fashion, or a combination of both.

Retrograde approach

The retrograde technique is the most simple and least invasive. It is done through a single ureteral catheter

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

that is advanced beyond the level of the lesion or stone. The main disadvantage of this technique is the limitation of outflow through or around this small stent, which can result in a rapid elevation of intrapelvic pressures. Therefore, this technique of irrigation is not recommended. In an attempt to avoid this complication, Kuwahara *et al*. used a computer-controlled, pressure-monitor intermittent pump (Figure 26.1A) [5]. This pump infuses fluid for 1 min, holds for 30 s, and then drains for 9 s. If the pressure increases beyond the preset limit (15 cmH_2O), the infusion stops. If the pressure increase is sustained for 5 s, the drainage valve opens. This system has not been widely used because it is prohibitively expensive; as such its safety and efficiency have not been properly evaluated. Without such a pump, a single ureteral catheter for irrigation is not recommended.

Several other techniques of retrograde instillation have been described. Dormia *et al*. [6] utilized concentric catheters placed in the ureter to facilitate the outflow from the kidney into the bladder (Figure 26.1B). Another less efficient technique is vesicoureteral reflux in a patient with an indwelling ureteral stent postureteral meatotomy [7]. Recently, a high-flow low-pressure irrigation system was described that uses an 8F pigtail catheter through a 12/14F ureteral access sheath (Applied Medical Systems, Rancho Santa Margarita, CA, USA). In an *in vitro* study, this system was found to be associated with significantly higher flow rates and lower pressures when compared with a single nephrostomy tube without ureteral catheters [8].

Antegrade approach

The ideal inflow and outflow is achieved in a percutaneous antegrade fashion through the use of two nephrostomy tubes, e.g. two Malecot catheters (16 or 18F) (Figure 26.1C). This configuration is versatile and can be used in most patients. In patients with struvite stones, which tend to form large, irregular pieces on fragmentation, an endopyelotomy stent (14/8.2F) provides excellent two-way outflow, decreases the volume of fragments that enter the ureter, and prevents its obstruction [9] (Figure 26.1D). Another method of preventing ureteral obstruction is the insertion of an indwelling double pigtail catheter when two Malecot nephrostomy tubes are used. Yet a simpler method of inflow and outflow in antegrade fashion through two nephrostomy sites is achieved with a circle tube (Figure 26.1E).

Two coaxial techniques of irrigation have been described. First, Hare and McOmish described a renal pelvic lavage set to irrigate different areas of the pelvis through a single nephrostomy site allowing both inflow and outflow [10] (Figure 26.1F). Once the Teflon sheath is in place, an inner 6.3 or 8.3F pigtail catheter is directed at the stone for inflow. Outflow, which is limited, occurs through the surrounding sheath and down the ureter. The second coaxial technique works well for upper ureteral stones [11, 12]. It is set up by inserting either a 5F ureteral or angiogram catheter over a wire through the lumen of an 18F Foley catheter, which serves as a nephrostomy tube (Figure 26.1G). The small inner catheter, which provides inflow, can be advanced so that its tip is adjacent to the stone, and the Foley catheter provides outflow. A simpler technique of irrigating the renal pelvis through a single nephrostomy site is the use of a three-way Foley catheter [13].

Combined approach

A combination of the antegrade and retrograde techniques can be achieved through the insertion of a percutaneous nephrostomy tube and ureteral catheter. The nephrostomy tube acts as an ideal outflow, while the ureteral catheter is used for instillation (Figure 26.1H). However, using both a ureteral catheter and a nephrostomy tube will severely reduce patient mobility. Therefore, a modified approach uses a nephrostomy tube to instill agents and an indwelling double pigtail ureteral catheter as a drainage catheter. The drawback of this approach is that the outflow through a ureteral catheter is much less efficient than that through a nephrostomy tube, and this modification is only ideal for small stones that dissolve quickly, e.g. uric acid stones.

Safety principles

All of the techniques described above should follow appropriate safety principles. Patients should have preoperative urine cultures and be treated with culture-specific antibiotics. Urine cultures should be negative prior to initiating irrigation and patients should be kept on antibiotics throughout the irrigation. Additionally, once the tubes are inserted, contrast studies should be performed 24 h later to rule out extravasation.

The irrigation with warm saline should start slowly at a rate of 30 mL/h. Providing the patient remains pain free and afebrile, the rate can be doubled every 2–4 h until the target rate of 120 mL/h is reached [13]. After 12–24 h of saline irrigation, the active agent is instilled at a rate of 30 mL/h and increased sequentially to 120 mL/h. Warming the irrigation solution has several advantages: it is more comfortable for the patient, avoids hypothermia, and may increase the effectiveness of therapy [14–16].

It is important to include an intrapelvic pressure monitoring system in all of the techniques described above. If renal pelvic pressures are uncontrolled, pyelovenous and pyelolymphatic backflow can lead to systemic absorption. Subsequently, the patient may suffer

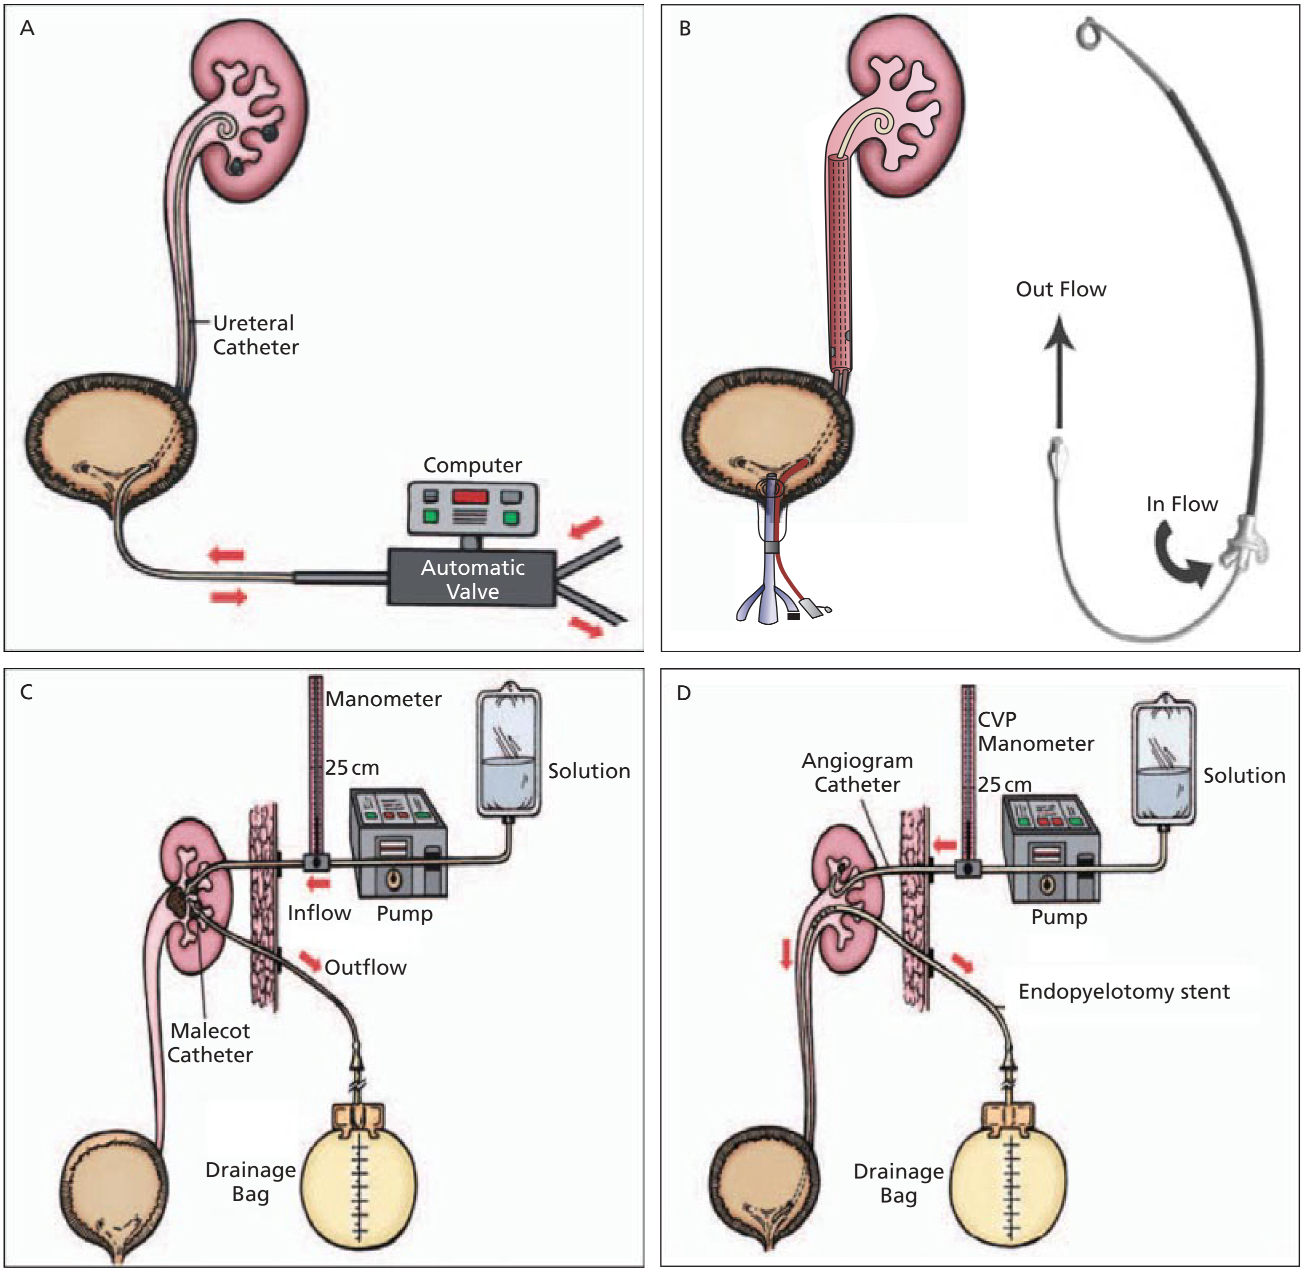

Figure 26.1 Irrigation configurations for chemolysis. (A) Retrograde ureteral catheter with computer-driven inflow/outflow (adapted from Fried and Smith [13] with permission). (B) Concentric catheters in kidney, ureter and bladder for trans-ureteral irrigation (adapted from Dormia *et al.* [6]; and Collins *et al.* [8]). (C) Dual Malecot catheters irrigation. (D) Nephrostomy inflow and universal/endopyelotomy stent outflow irrigation for struvite stones.

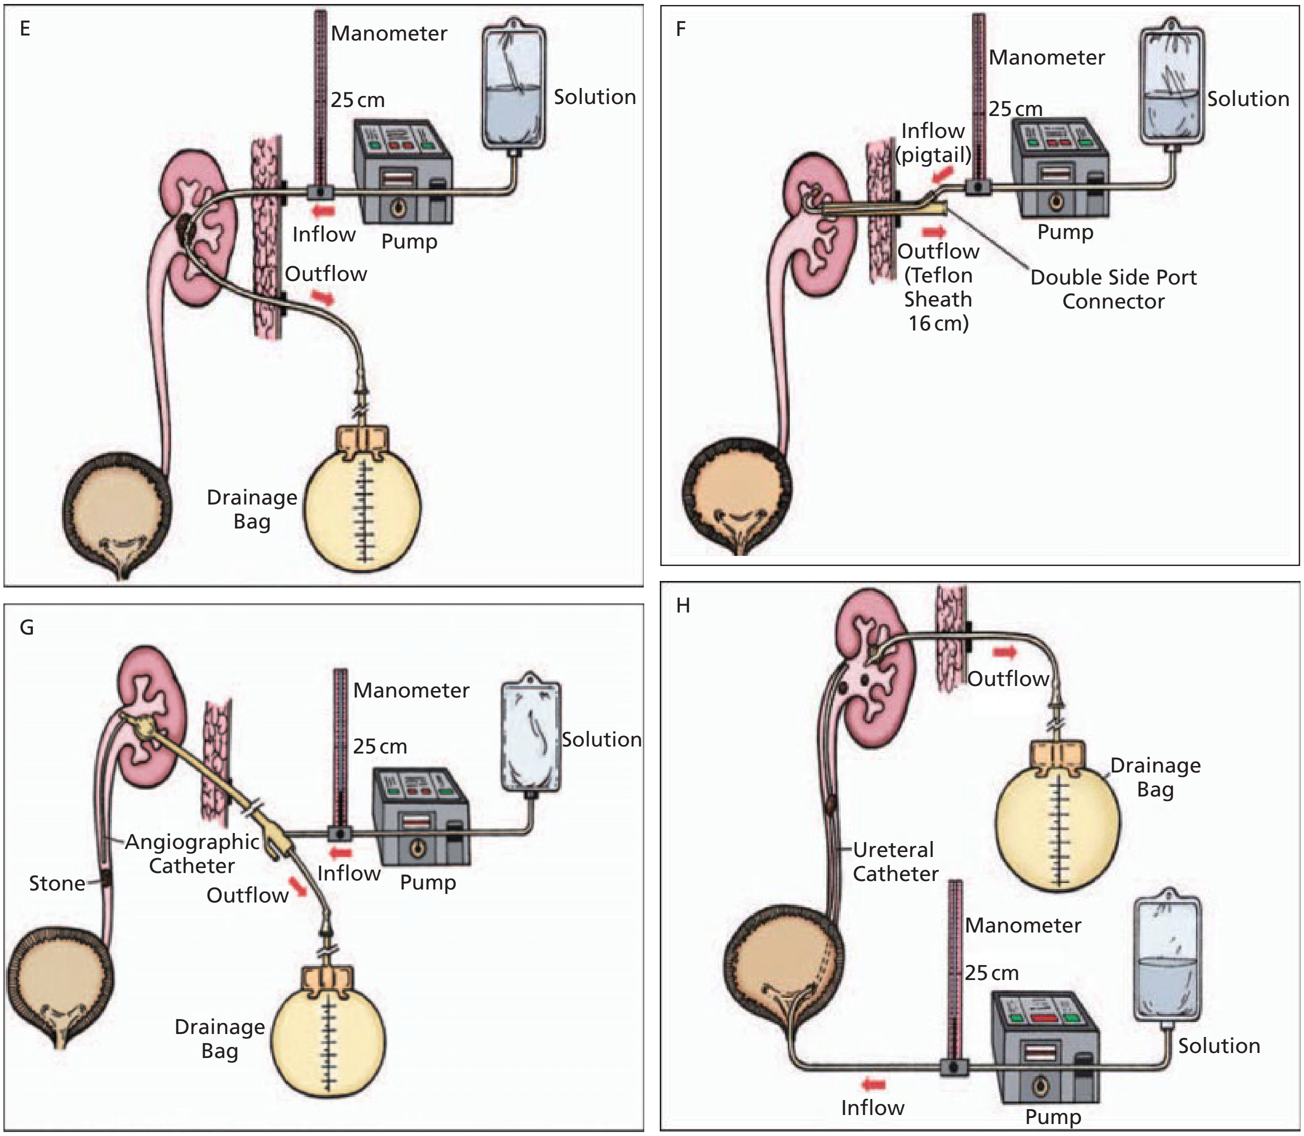

Figure 26.1 *Continued* (E) Circle tube for irrigation chemolysis. (F) Coaxial technique of ureteral catheter through a Foley catheter. (G) coaxial technique of ureteral catheter through a Foley catheter. (H) retrograde ureteral catheter inflow and nephrostomy outflow.

agent-specific systemic toxicities, or changes in serum chemistries when the irrigant solution is nontoxic [17]. Therefore, to prevent pyelovenous backflow, the intrapelvic pressure should not be allowed to rise above 25 cmH_2O [18]. The simplest method uses a central venous pressure (CVP) manometer connected to the inflow line, which is both readily available and familiar to nursing staff. Unfortunately, this is an open system that is amenable to contamination or overflow spills. Furthermore, it requires continuous monitoring since there is no preset pressure alarm or automatic shut-off for high pressures (more than 15 cmH_2O). A better alternative is a closed continuous infusion pump that provides a continuous display of the intrapelvic pressure and will sound an alarm and shut off if the preset limit is exceeded (CareFusion, San Diego, CA, USA) [6]. Regardless of which pump is used; the patient should be taught how to immediately turn off the pump in case of flank pain or fever.

Chemolysis of urinary calculi

Stone dissolution through chemolysis remains an option in the treatment of urolithiasis, even with the advent of more sophisticated modalities. Chemolytic agents can achieve benefit through either primary or secondary dissolution. Primary dissolution is when chemolytic agents are used as initial therapy to dissolve stones

completely or partially. This may be an option in patients unfit for general anesthesia. Secondary dissolution may be useful in patients with residual fragments after some other primary therapy. In this context, chemolysis may render the patient stone free, thus reducing the potential for recurrences or more invasive interventions.

For effective chemolysis, the irrigant must have several important characteristics: (1) be compatible with biologic tissue and of limited toxicity; (2) have minimal systemic absorption in order to limit potential toxicity; (3) dissolve calculi and their fragments quickly to reduce treatment burden for the patient; and (4) do not precipitate causing secondary stone formation. Additionally, an ideal irrigation system must provide for free flow of irrigant to a targeted area, while maintaining low renal pelvic pressures to prevent bacteria from entering the bloodstream and avoiding renal damage [17].

Unfortunately, stone dissolution through chemolysis has several limitations. Some stones may require long treatment periods, which may necessitate prolonged hospital admission and patient discomfort. The efficacy of stone dissolution is dependent on many stone-specific factors. For example, uric acid and struvite amorphous minerals dissolve much faster than highly crystalline salts such as calcium oxalate. Likewise, stone size and shape will determine rate of dissolution. Large stones will dissolve more slowly than the same volume of smaller stones as the surface area is greater in the latter [19, 20]. These variables can make it difficult to predict the necessary length of treatment *a priori*. In addition, the choice of chemolytic agent will depend on stone type and stone composition must be determined prior to chemolysis. When stone fragments are not available, surrogate methods of determining stone composition, such as computed tomography (CT) characteristics or the composition of previous stones, must be used to determine the agent of choice [17, 21, 22].

Uric acid stones

Almost all individuals who form uric acid stones have persistently low urinary pH (<5.5) and most excrete normal amounts of uric acid [23, 24]. The acid–base properties of uric acid stones render them amenable to dissolution therapy. Uric acid is a weak organic acid with a pKa of 5.35 in urine at 37°C. At this pH, half is present as the undissociated acid and half as the urate anion. Since urate is more soluble than uric acid, raising the urinary pH within the physiologic range has a profound effect on how much uric acid/urate can be dissolved. For example, a urine sample containing 800 mg/L total urate will have 600 mg/L uric acid at pH 5.0 but less than 100 mg/L at pH 6.5. The latter figure is well below the solubility limit of uric acid so that a solution above pH 6.5 can dissolve a uric acid calculus [18]. Any solution above pH 7 is likely to be effective but higher urinary pH solutions may have a tendency to calcify the stone, particularly if sodium bicarbonate is used as the base [25]. Increasing the urinary volume further enhances the therapeutic efficacy of alkaline medications [26]. In addition, decreasing the oral purine load from dietary sources can effectively help treat patients, because 40–60% of excreted uric acid is derived from exogenous sources. Regardless of the method chosen, urine pH should be monitored with pH strips to optimize therapy. It is also important to follow serum and urine uric acid levels, especially in those with recurrent calculi.

Systemic agents

Systemic alkalinization is generally achieved with oral or intravenous therapy. The most popular agent is sodium bicarbonate at a dose of 650–1000 mg three to four times daily. An alternative preparation, if the sodium load is too great, is potassium citrate administered at 15–30 mEq three to four times daily. Intravenous alkalinization is more effective than the oral route; urinary pH is elevated more quickly, to a higher degree, and more reliably. This technique, however, is typically reserved for hospitalized patients with acute episodes of renal colic and obstruction. One-sixth molar lactate solution has been demonstrated to dissolve uric acid stones even when they are causing ureteral obstruction [27]. Lactated Ringer's solution with one to two ampoules of sodium bicarbonate added per liter is an acceptable alternative. The infusion rate (usually 50–100 mL/h) is titrated to a urinary pH of 7.0–7.5, which occurs within 4 h. Cardiac and hypertensive patients must be monitored for the large sodium load in these solutions.

Several other oral therapies have been suggested to facilitate dissolution therapy. Sterrett *et al*. demonstrated that acetazolamide, a carbonic anhydrase inhibitor, was effective in increasing the urinary pH in patients with uric acid and cystine stone formation who were already taking potassium citrate [28]. Caution must be taken when prescribing acetazolamide because it can be poorly tolerated and can induce calcium phosphate stone formation. A dose of 250 or 500 mg is taken at bedtime to maintain urine alkalinity during sleep. In cases of hyperuricosemia and hyperuricosuria, allopurinol should be added to inhibit the production of uric acid through inhibition of the enzyme xanthine oxidase.

Chemolytic agents

Since the urinary pH can usually be raised to at least 6.5 with oral or intravenous alkaline salts, medical therapy is ordinarily the treatment of choice for uric acid stones

[18, 24, 26]. There are clinical situations in which oral or intravenous therapy is not possible, such as in patients who are noncompliant, or have chronic renal failure or an ileostomy, and these patients may benefit from direct chemolytic therapy. Additionally, if a large amount of residual fragments is present after an initial therapy, direct chemolysis is a viable option.

The most common alkalinizing agents are sodium bicarbonate solution (pH 7.0–9.0), tromethamine (THAM, pH 8.6), and THAM-E (pH 10.5). Sodium bicarbonate solution is inexpensive and can be prepared easily by adding two to four ampoules (44 mEq each) to each liter of irrigant solution (normal saline solution or water). With this solution, there is no value in increasing the final urinary pH to greater than 7.5. In fact, higher pHs may be detrimental to stone dissolution because phosphatic and sodium urate encrustations may form a coating on stones [29]. The THAM solutions do not cause such mineral deposits and in animal models have been shown to cause more rapid stone dissolution than sodium bicarbonate [25]. THAM-E is slightly more effective than THAM because of its higher pH, but it causes more irritation and potential damage to the epithelium [30, 31]. Therefore, for uric acid chemolysis, THAM appears to be the agent of choice [18] (Table 26.1).

If a uric acid staghorn calculus is present, pretreatment with extracorporeal shock-wave lithotripsy (ESWL) may increase the stone surface area and facilitate dissolution. Unlike struvite and cystine stones, it is unusual to need prolonged irrigation to manage uric acid stones.

Cystine stones

Cystinuria is an autosomal recessive disorder of dibasic amino acid transport in the kidney that leads to crystallization of poorly soluble cystine in the urine [32]. Between 3% and 59% of those who are homozygous for the trait will produce stones [33]. The disease is more severe in men than in women in terms of early appearance and number of stones. Although the incidence of cystine stones is only about 0.9%, they rank third in terms of rate of recurrence [34]. Treatment of cystine stones continues to be one of the most challenging therapeutic dilemmas in endourology because of their high frequency of recurrence, resistance to ESWL, difficulty in localization, and the inadequate effect of oral chemolysis [35].

Due to the difficulties in treating cystine stones, much emphasis has been placed on prophylaxis. The solubility of cystine, like all amino acids, is pH dependent. Therefore, the production of alkaline urine can prevent cystine precipitation in the urine. A significant increase in cystine solubility begins to occur when urinary pH exceeds 7. For example, at pH 8, cystine solubility increases to approximately 1000 mg/L [36]. However, a significant drawback of urinary alkalinization is increased risk for calcium phosphate precipitation with pH above 7.5 [37]. For this reason, a urinary pH of 7.5 is recommended [36]. It is recommended that this alkaline urinary pH must be maintained at night while the patient sleeps. The use of the potassium salts of citrate and bicarbonate may be more effective than the analogous sodium compounds because the presence of a sodium ion increases cystine excretion in the nephron. As such, a low sodium diet may be useful in the management of cystinuria [38].

Cystine is composed of two cysteine molecules joined by a disulfide bond and its dissolution requires alkalinization and splitting of the disulfide bond. This can be accomplished through either oral therapy or direct chemolytic therapy. D-Penicillamine, the first oral agent used for cystine stones, is a disulfide exchange resin that facilitates splitting of the disulfide bond through the thiol exchange reaction, forming mixed disulfides, and also decreases urinary excretion of cystine. The exchange reaction forms penicillamine disulfide–cysteine, which is 50 times more soluble than cystine [39] and is readily cleared through the urine. D-Penicillamine is administered as 1–2 g in four divided doses, starting with a small dose and increasing as tolerated. Side effects of the drug include leukopenia, thrombocytopenia, gastrointestinal disturbances, skin rashes, proteinuria and nephrotic syndrome, neuropathies, and abnormalities of taste and smell. D-Penicillamine has been reported to dissolve even large stones when combined with alkalinization but its potential side effects severely limit its usefulness.

α-Mercaptopropionylglycine (MPG) is another disulfide exchange resin with fewer side effects than D-penicillamine; it also appears to be more effective [40]. The usual dose of MPG is 600–1800 mg/day in four divided doses. Simultaneous treatment with oral sodium bicarbonate increases the effectiveness of this preparation because the disulfide exchange reaction is more active at higher pH levels.

Oral acetylcysteine, MPG, and D-penicillamine are much more effective in preventing the formation of cystine calculi than in dissolving them. When used for direct chemolysis, however, they are potent dissolution agents. During direct irrigation, the solution bathing the stone will have a much higher concentration of the active agent. The pH of the solution is likewise more easily controlled, thereby facilitating the thiol exchange reaction [13].

Chemolysis monotherapy would require lengthy durations of irrigation for most stones. Approximately 9 days are required to dissolve a 1-cm cystine calculus. This irrigation time could be diminished with combined therapy with ESWL or percutaneous nephrolithotomy

Table 26.1 Results of direct chemolysis for uric acid and cystine stones.

Uric acid calculi

(PCNL), which reduce the stone burden and increase the surface area of the remaining fragments. Stones less than 1.5 cm in diameter may be treated initially with ESWL. If successful fragmentation occurs, repeat ESWL or medical management may be sufficient as follow-up therapy. Otherwise chemolysis alone or combined with PCNL is appropriate. For stones greater than 1.5 cm, PCNL is the initial procedure of choice. Residual calculi, which are likely to remain, can be effectively treated with chemolysis and additional PCNL or ESWL sessions. Simultaneous oral therapy should be implemented in all cases [13] (Table 26.1).

If the stones appear extremely resistant to therapeutic measures, the possibility of a mixed stone should not be overlooked. Hydroxyapatite, struvite, calcium oxalate, and calcium phosphate contaminants have been present in 14–46% of cystine calculi analyzed in some studies [41].

In summary, although cystine urinary calculi continue to present a formidable challenge to urologists, successful eradication without open surgery may be accomplished with chemolytic techniques in conjunction with minimally invasive fragmentation procedures.

Struvite stones

Struvite stone formation typically occurs in patients with recurrent urinary tract infections (UTIs) and retained urine. Predisposing factors include urinary tract obstruction, chronic indwelling catheter, urinary diversion, and neurogenic voiding dysfunction [42]. Most commonly, staghorn stones are composed of a mixture of struvite (magnesium ammonium phosphate) and calcium carbonate apatite. In fact, hypercalciuric patients begin with calcium oxalate stone formation and develop superimposed infection with struvite deposition [43, 44]. Struvite calculi are typically referred to as infection stones because of their strong association with UTIs. Silverman and Stamey identified *Proteus* as the dominant microorganism in 72% of isolates from stone

formers [45]. Urease produced by such bacteria leads to hydrolysis of urea to ammonium, hydroxide, and bicarbonate, which increase the urine pH (>7.2). This alkaline urine, in the presence of trivalent phosphate, results in struvite crystal formation [46]. Other urease producers include *Klebsiella*, *Pseudomonas*, and *Staphylococcus* species [45, 47]. However, the most ubiquitous uropathogen, *Escherichia coli*, only rarely produces urease and thus is an infrequent cause of staghorn calculi [48].

Struvite stones are characterized by their large size and exceptionally rapid growth. It is not uncommon for a staghorn calculus to involve the entire renal pelvis and calyces, nor for it to be formed within a 4-week period [42].

Management of struvite stone disease is one of the most frustrating problems in urology as efforts to eradicate such stones often have suboptimal success rates. The problem is not only ridding the patient of the calculi but also sterilizing the urine. Persistence of infection was estimated to occur in approximately 40% and is believed to be responsible for many of the stone recurrences [49]. The presence of small stone particles with embedded bacteria serves as a nidus for new stone formation and rapid recurrences. Therefore, postoperative irrigation therapy has been proposed to potentially reduce struvite stone recurrences [50, 51]. Oral chemolysis is available primarily in the form of urease inhibitors. Acetohydroxamic acid (AHA), the most commonly used agent, was identified as an irreversible urease inhibitor by Fishbein and Carbone [52]. The drug acts synergistically with several antibiotics, sterilizing the urine more rapidly. Its clinical usefulness has been demonstrated in double-blind studies but serious side effects precluded its use in patients in spite of these being reversible and dose related [53–55]. The usual dose is 250 mg orally three times daily to be reduced to twice daily for mild renal impairment, and it is contraindicated in patients with severe renal insufficiency and in pregnancy. The most commonly reported side effects are hemolytic anemia, neurosensory deficits, and thrombophlebitis. Headache, gastrointestinal upset, weakness, and flushing sensation after alcohol ingestion have also been reported [56]. Yet, it is the only Food and Drug Administration (FDA)-approved urease inhibitor available today [57].

Systemic oral chemolytic agents are seldom effective in reducing stone burden on their own and direct chemolysis of struvite calculi is a far more effective method of dissolution. Suby *et al*. presented the first application of direct chemolysis to struvite calculi; however, the initial solution was too irritant for urothelium to be clinically used [58, 59]. Suby's solution G, formed by the addition of magnesium to the previous formulation, has similar efficacy but decreased mucosal irritability (Table 26.2). Hemiacidrin (Renacidin), a modification of Suby's solution, is a multielectrolyte solution introduced by Mulvany [60] (Table 26.2). The acids present in this solution provide hydrogen ions and citrate to form soluble complexes with phosphate (phosphoric acid) and calcium (calcium citrate) from the stone (Table 26.3). Magnesium undergoes ion exchange with calcium present in the stone, enhancing dissolution while reducing irritation. The solubility of struvite is markedly increased at a pH less than 5.5, which occurs with each of the three variants of Suby's solution. This finding was confirmed in an *in vitro* study by Jacobs *et al*. [61].

Table 26.2 Composition of different chemolytic agents.

	Suby's solution		
Compound	G	M	Renacidin
Citric acid (g)	32.3	32.3	28.2
Magnesium oxide (g)	3.8	3.8	0
Sodium carbonate (g)	8.84	8.84	0
Calcium carbonate (g)	0	0	1.0
D-Gluconic acid (g)	0	0	5.0
Magnesium hydrocarbonate (g)	0	0	14.8
Magnesium acid-citrate	0	0	2.5
Water (mL)	1000	1000	1000
pH	4.5	4.0	4.0

Infectious complications are known to occur as a result of dissolution therapy. Renacidin and Suby's solutions have been implicated as the cause of urosepsis and death due to the release of large amounts of viable bacteria from stones as they dissolve. Therefore, it is critically important to stop treatment once fever occurs and until any infection has been adequately treated. The presence of catheters and extensive use of antibiotics can also facilitate fungal infection. Replacing the irrigation fluid with amphotericin B (50 mg/500 ml H_2O) at a rate of 125 mL/h generally clears the funguria in less than 72 h. Chemolysis irrigation can resume once urine cultures have been negative for 24 h.

Calcium stones

Calcium-based calculi constitute about 80% of all urinary tract stone calculi, of which about 80% are calcium oxalate stones [62]. Yet, they are the least amenable to chemolysis. The strong acids required to dissolve this compound cannot be safely used in humans. Only chelating agents have successfully been used *in vivo* to

Table 26.3 Results of direct chemolysis of struvite calculi.

dissolve these types of stones. Ethylene-diamine-tetra-acetic acid (EDTA) is the most commonly used solvent, and has had moderate success in humans [63, 64] in spite of the significant urothelial injury reported [65]. EDTA is a polyvalent molecule which binds calcium through its two amine and four carboxyl groups. This sequestration dissolves the calcium component of the stone, thus reducing stone burden. Complete stone dissolution of over 50% in 260 patients treated with EDTA was reported [66]. Early use of this solution after stone formation is associated with a better response rate. These authors also used 0.25% lyophilized papain to dissolve the matrix component of the stones. EDTA solutions are not widely used, primarily because they can cause urothelial injury.

Summary

In summary, the choice of chemolytic agent and method of administration is dependent primarily on stone

composition and should be tailored to the individual clinical scenario. There are several chemical means to increase the solubility of a stone. Manipulation of the pH is most commonly used; however, other modalities include disulfide rearrangement and cation chelation [18]. Manipulation of pH works particularly well for uric acid stones since they are 11 times more soluble at a pH of 6.5 than of 5.0 [24, 67]. An effective therapeutic pH of slightly above 7.0 can often be achieved with oral therapy alone but direct chemolysis can be considered for large stone burden [68]. Struvite stones will dissolve at a pH of 4.9, but at a rate too slow to be clinically useful [69]. Therefore, other approaches, including systemic chemolysis with urease inhibitors or direct chemolysis with Ranicidin solution, should be considered. The solubility of cystine is increased in alkaline urine, but is higher than that required to dissolve uric acid (pH of 7.5). At this pH there is an increased the risk of secondary precipitation. Therefore cystine stones can be more effectively treated with direct chemolysis using disulfide exchange resins. Calcium stones are the least amenable to chemolysis, but some success had been shown with EDTA chelation; however, toxicity to the urothelium limits the usefulness of this approach.

Chemotherapy and immunotherapy for upper tract transitional cell carcinoma (see also Chapter 28)

Nephroureterectomy with excision of a bladder cuff is the gold standard of care for upper tract TCC. Organ-preserving procedures that include ureteroscopic or percutaneous resection and segmental ureterectomy have been reserved typically for patients with solitary kidney, bilateral disease, poor renal function, small tumor burden, and low-grade disease [70]. The advent of improved endourologic techniques facilitates access to any part of the upper tract so that tumor location is no longer a limiting factor. Adjuvant topical immunotherapy or chemotherapy post endoscopic resection of upper tract TCC has been used in an attempt to reduce the risk of recurrence and progression. Bacillus Calmette-Guérin (BCG), mitomycin-C (MMC), and thiotepa are the most common agents used.

There are several important considerations when using a topical chemotherapeutic agent as compared to a chemolytic or antifungal agent. In terms of mode of instillation, the antegrade approach has been hypothesized to maximize contact between the agent and the urothelium, and minimize contact interference between the agent and retrograde ureteral stent [71]. However, this approach predisposes the patient to the theoretical risk of nephrostomy tract seeding. Nevertheless, there are no available data to advocate one approach over another [72]. High pressures in the renal pelvis and extravasation after BCG application must be avoided. For the antegrade approach, the patency of the ureter to the bladder must be verified before each perfusion using contrast. This also excludes any pyelovenous or pyelolymphatic backflow. If the nephrostomy tract was used for resection of the upper tract TCC, initiation of adjuvant BCG therapy is usually delayed for 2–3 weeks to allow for healing of the urothelium, thereby decreasing the risk of systemic side effects. Furthermore, BCG must not be instilled in the presence of gross hematuria for fear of severe systemic complications.

Oosterlinka *et al*. described a method to instill BCG in an antegrade fashion into the upper tract. A dose of 360 mg Immuno BCG Pasteur F (Institut Pasteur, Paris, France) or 243 mg Immucyst (Sanofi Winthrop, Meyriez, Switzerland) is dissolved in 150 mL of normal saline. This is the same concentration but three times the dose and volume that is used intravesically. The flask is placed 20 cm above the level of the kidney of the supine patient. A continuous flow of approximately 1 mL/min (15–20 drops/min) is maintained for 2 h [73]. After the perfusion is finished, the nephrostomy tube is clamped. Patients receive ampicillin prophylactically and are kept under hospital surveillance for one night. BCG instillations are repeated on a weekly basis for 6 weeks [74].

For the retrograde approach, it is advised not to use ureteral catheters larger than 5F to allow drainage along the ureteral catheter to the bladder. It is very helpful to use fluoroscopy, at least for the first session, to establish proper catheter position and rule out unexpected anatomic difficulties. Free flow of urine from the catheter or retrograde injection of contrast verifies proper position in the collecting system. Ureteral catheters are secured via silk ties to a Foley catheter placed to drain the bladder and brought to rest at the bladder neck. The Foley catheter is either left to straight drainage or elevated over the bedrail to allow some collection into the bladder, depending on whether simultaneous bladder exposure is desired. It may also be capped during treatment if formal intravesical instillation is performed at the same time. The viscosity of the full-dose BCG suspension is such that it will not spontaneously drip under gravity instillation through such a small 4F catheter. Therefore, low-dose BCG (one-third to one-tenth standard dose) plus interferon-α (50–100 million units) in 50 mL normal saline is used with the retrograde approach [70]. The patient is positioned supine and the medication is suspended in an intravenous bag no more than 30 cm above the kidney level. Medication is instilled via microdrip tubing at the rate of one drop per 2 s, corresponding to a rate of approximately 30 mL/h. The drug is only instilled via gravity and should never be placed on a pump for fear of increased intrarenal pressure. At the end of treatment, the Foley catheter is drained and then removed with the attached ureteral catheters.

Table 26.4 Studies evaluating topical therapy for upper tract urothelial cancer (adapted from Rastinehad *et al*. [102]).

Study	Indication	Number of patients (renal units)	Therapy	Mean follow-up (months)	Comments
Jarret *et al*. [91]	Adjuvant to percutaneous treatment	17 (19)	BCG	55	No significant improvement in survival with BCG
Elliott *et al*. [92]	Adjuvant to endoscopy	18	Thiotepa, MMC, BCG	N/A	No difference in outcome between treated and untreated
Yokogi *et al*. [93]	CIS	5 (8)	BCG	10–46	NED in 5/8 renal units
Martinez-Pineiro *et al*. [94]	Adjuvant to endoscopy	32 (36)	BCG, MMC, thiotepa, IFN-α	30.7	12.5% recurrence with BCG, 14.2% with MMC, 60% with thiotepa; no significant findings with IFN-α
Keeley and Bagley [108]	Adjuvant to ureteroscopy	19 (21)	MMC	30	35% complete response; 27% partial response, and 38% no response
Patel and Fuchs [95]	Adjuvant to ureteroscopy	13 (17)	BCG	14.6	NED in 15/17 renal units
Nishino *et al*. [96]	CIS	6 (8)	BCG	22	NED in 8/8 renal units
Nonomura *et al*. [97]	CIS	11	BCG	NA	NED in 7/11 patients
Chen *et al*. [98]	–	15 (23)	BCG/IFN-α	15.3	70% response rate (74% for CIS)
Miyake *et al*. [99]	CIS	16	BCG	30	NED in 13/16 patients
Thalmann *et al*. [71]	Not eligible for open surgery	37 (41)	BCG	42	87% recurred or progressed; 32% CIS disease-free
Palou *et al*. [100]	Adjuvant to percutaneous treatment	19	BCG in 14, MMC in 5	51	57.9% recurrence in treated patients vs 26.7% in untreated patients
Katz *et al*. [101]	CIS, adjuvant to endoscopy	10 (11)	BCG–IFN-α	24	80% complete response, 20% partial response
Rastinehad *et al*. [102]	Adjuvant to endoscopy	(50)	BCG	80.8	No statistical significance between any of the treated and nontreated groups

A novel approach to gain upper tract BCG exposure was reported by Herr in a patient with grade 3 renal pelvic TCC and carcinoma *in situ* (CIS) in an ectopic solitary kidney [75]. After open surgical resection, a freely refluxing pyelovesical anastomosis was constructed. The patient received six weekly installations of BCG and remained recurrence free at 13 months follow-up. Ramsey and Soloway reported a similar approach accomplished by creating a freely refluxing system after autotransplantation of a solitary kidney with recurrent pyelocalyceal TCC [76]. For patients with refluxing urinary diversions, MMC or BCG can be delivered via a catheter placed into the conduit or reservoir.

A substantial proportion of patients with endoscopically managed upper tract TCC will develop a recurrence. Adjuvant topical immunotherapy or chemotherapies have been used in an attempt to reduce the risk of tumor recurrence and are often reserved for patients with large, multifocal, or residual tumor. The true benefit of topical therapy, either as a primary treatment for CIS or as adjuvant therapy for endoscopically treated upper tract TCC, is difficult to assess due to the heterogeneous groups of patients receiving such therapy (solitary vs multifocal disease, primary vs recurrent, low vs high grade) [70]. These retrospective case series are summarized in Table 26.4. Here we discuss the three most common agents used.

Bacillus Calmette-Guérin

BCG, a live attenuated strain of *Mycobacterium bovis*, first indicated as a tuberculosis vaccine, has had widespread use in intravesical immunotherapy since the 1970s [77]. It has since become the drug of choice for treatment of CIS, in addition to being an effective prophylactic agent against recurrences following transurethral resection of high-grade superficial bladder tumor [78–80].

The mechanism of action has been intensively investigated. It binds directly to fibronectin within the urothelium, leading to direct stimulation of cell-based immunologic response. Numerous cytokines involved in the initiation or maintenance of inflammatory processes, including tumor necrosis factor-α, granulocyte–macrophage colony-stimulating factor, interferon (IFN)-γ, and interleukins are induced. This immunologic response activates cell-mediated cytotoxic mechanisms that are believed to underlie the efficacy of BCG in the prevention of recurrence and progression [81].

Most patients develop an inflammatory immunologic response to BCG during a typical induction course of six weekly instillations. Optimal dosing and instillation schedules have not yet been established, but some trials have demonstrated that a reduced dosing regimen (one-third dose) may be as effective as standard dosing but with fewer side effects [82–84]. Studer *et al*. first demonstrated the feasibility and efficacy of using BCG in the upper urinary tract [74]. They treated 10 renal units that had cytologic evidence for CIS with BCG delivered via a percutaneous nephrostomy tube. In seven of the 10 renal units, urinary cytology reverted to negative. Though complications were few, BCG sepsis did develop in one patient, necessitating cessation of therapy. Since then, several studies have demonstrated the safety and efficacy of intracavitary topical therapy in combination with endoscopic management in upper tract TCC (Table 26.4) [71, 85–102].

There have been no randomized trials comparing endoscopic treatment of upper tract TCC with or without BCG. In one of the largest series of adjuvant therapy for upper tract TCC, Thalmann *et al.* retrospectively evaluated the results of BCG therapy in patients not eligible for nephroureterectomy [71]. Thirty-seven patients (22 with CIS, 15 with Ta or higher after endoscopic resection) were treated with six weekly perfusions of BCG via a 10F nephrostomy tube. At a median follow-up of 42 months, 14 patients (38%) died of urothelial cancer, 11 (29%) of other causes, and 12 (33%) were alive. Other adverse outcomes included severe septicemia in two patients. There was no seeding of the nephrostomy tube tract and dialysis was avoided. Overall median survival was 42 months (range 1–137 months) with median recurrence-free survival of 21 months (range 1–137 months). The authors noted that this was a patient population with a poor prognosis, and while BCG extended survival for some patients, it did not provide cure except for in some patients with CIS. Of the patients treated in the adjuvant setting for papillary disease, only 13% remained without recurrent or progressive disease, with a median time to recurrence of 10 months. In contrast, treatment of CIS resulted in 32% of renal units remaining disease free for a median follow-up of 51 months. Results achieved with intracavitary topical therapy have been varied.

Some authors have found intracavitary topical therapy to be beneficial in terms of recurrence and disease-free survival, but not overall survival. Orihuela and Smith found a recurrence rate of 80% among patients who did not receive supplemental BCG versus a recurrence rate of 16.6% among those who did [86]. However, an update of their series could not ultimately demonstrate a survival advantage with the addition of adjuvant BCG [91]. Martinez-Pineiro *et al*. have shown an advantage of adding BCG or MMC after endoscopic treatment of upper tract TCC [94]. These authors reported a recurrence rate of 50% among patients with grade 2 or 3 disease who were not treated with adjuvant therapy versus 27.7% among a similar group of patients who received some form of adjuvant therapy. The authors used several drugs, including BCG, MMC, 5-fluorouracil, thiotepa, and interferon-α, but only BCG and MMC were promising. Katz *et al*. published their initial experience with BCG plus IFN-α2b [101]. With a median follow-up of 24 months, 80% of patients demonstrated a complete response, while 20% had a partial response (decrease in tumor size, number, or both). The authors reported that the treatment was well-tolerated in the office setting and did not note any complications.

In contrast, other studies have not shown a significant difference between patients treated with adjuvant MMC or BCG compared to those undergoing endoscopic treatment alone [92, 103]. Hayashida *et al*. reported a 50% disease recurrence rate at a follow-up of 50.9 months after intrarenal perfusion of BCG with endoscopic treatment [104]. This high recurrence rate occurred despite an initial return of cytology results to normal and all of these patients suffered cancer-specific mortality. Rastinehad *et al*. retrospectively studied 133 renal units treated by percutaneous resection for upper tract TCC [102]. Eighty-nine renal units treated primarily by percutaneous resection were then analyzed. Fifty renal units received adjuvant BCG therapy 2 weeks after endoscopic management for a total of six courses. Recurrence was defined as a positive biopsy result after the third-look nephroscopy. Overall median follow-up was 40.8 months. There was no statistical difference with regard to tumor grade or stage between treated and nontreated groups. Recurrence, time to recurrence, and progression of disease among renal units treated

with BCG were subselected by grade and compared with the corresponding nontreated group. There was no statistical significance demonstrated between any of the treated and nontreated groups. The authors concluded that there is no overall oncologic benefit in the administration of adjuvant BCG with regard to disease recurrence, interval to recurrence, and progression of disease in the treatment of upper tract TCC.

There are several known complications of cavitary BCG therapy. Persistent fever after BCG administration has been reported in three of 59 (5.1%) patients in a combined series, though this resolved in all cases with appropriate antimicrobial therapy [91, 94, 103]. Granulomatous involvement of the upper urinary tract may occur in up to 25% of patients after BCG administration; however, the significance of these findings is not yet clear [105].

The controversy and variability among studies addressing the intracavitary topical use of BCG is likely the result of nonrandomization and the bias in patient selection for this modality of treatment. Some authors treat all patients with adjuvant therapy while others treat only high-risk patients. Furthermore, it is important to note that several products contain different substrains of BCG. There is variability of BCG organisms per milligram of vaccine with different substrains and from lot to lot within the same substrain [106, 107]. Thus, the true efficacy of adjuvant BCG therapy for upper tract TCC has yet to be adequately evaluated. However, secondary effects of therapy seem to be generally well-tolerated among patients.

Mitomycin-C

Less information is available on the use of intracavitary MMC topical treatment compared with BCG. MMC is a 334-kDa alkylating agent that inhibits DNA synthesis. Because of its moderately high molecular weight, there are few problems with transurothelial absorption. Therefore, side effects such as myelosuppression are rare. The typical dosage varies from 20 to 60 mg per instillation, and the most commonly used dose is 40 mg in 40 mL of saline or sterile water administered weekly for 8 weeks.

Keeley and Bagley reported on adjuvant MMC (40 mg in three divided doses via ureteral catheter) in 19 patients (21 renal units) for high volume, recurrent, or multifocal urothelial carcinoma [108]. No systemic side effects occurred during or after treatment with MMC. Thirty-five percent had a complete response, 27% a partial response (reduction in tumor size >50%), and 38% no response. Tumors with a complete response were of similar size and grade as those that did not respond as well. After a mean follow-up of 30 months, none of the patients suffered local disease progression or died of the disease; however, nearly all the patients required repeat ureteroscopic treatment for residual or recurrent disease. At least one case of toxic agranulocytosis has been reported following absorption of extravasated MMC [94].

An alternative experimental treatment regimen for upper tract TCC in refractory patients is sequential gemcitabine and MMC. The medication dosage is 1 g gemcitabine in 50 mL phosphate-buffered normal saline, then 40 mg MMC in 40 mL of sterile water. The gemcitabine is instilled, followed immediately by the MMC. In a group of patients with treatment-refractory nonmuscle invasive bladder cancer, eight of 37 had upper tract involvement. Gemcitabine alone was effective in only one of 14 patients (7%), while sequential treatment with gemcitabine followed by MMC was successful in 13 of 23 patients (57%) [109]. The rationale for sequential treatment is that gemcitabine is too acidic and will affect MMC activity if the two are given together. Additionally, gemcitabine primarily kills cells undergoing DNA synthesis (S-phase), while MMC is noncell phase-specific and leads to cell cycle arrest. Gemcitabine is given first, followed by MMC to maximize therapeutic efficacy. Some authors consider that outcome can be improved by overnight fasting, use of sodium bicarbonate to reduce drug degradation, and an increased concentration of gemcitabine to 40 mg in 20 mL [110].

Thiotepa

Thiotepa (triethylenethiophosphoramide) is an alkylating agent and is not cell-cycle specific. Introduced in 1961, thiotepa is the oldest and one of the least expensive intravesical drugs. Doses range from 30 to 60 mg in 30–60 mL of sterile water or saline. The lower dose appeared to be as effective as the higher one in a comparative study when the concentrations were the same [111]. The Medical Research Council Working Party on Urological Cancer reported that the lower concentration of 30 mg in 50 mL was not effective [112]. The usual regimen consists of six to eight weekly instillations. A low molecular weight of 189 kDa allows partial absorption through the urothelium with possible systemic toxicity. Myelosuppression is a risk, especially with the 60 mg dose. Complete blood count is obtained before each instillation and treatment is delayed if necessary. Thiotepa has not been as well-evaluated as many other topical agents as adjuvant therapy after endoscopic management of upper tract TCC [92, 94].

Summary

Although the cumulative experience appears encouraging regarding the efficacy of topical immunotherapy, especially against CIS, no individual study has shown

statistical improvement in terms of survival and recurrence rates. This could be the result of insufficient numbers of patients to examine the clinical significance of the drugs and delivery of inadequate drug concentrations over an appropriate period of time to enable a clinical response when compared with lower tract TCC [7]. There is no doubt that further studies are required to settle this issue. It is apparent that most published series regarding percutaneous adjuvant therapy involve few patients with short follow-up, making it difficult to reach any meaningful conclusion. No protocol of treatment has as yet been accepted. None of the published series has evaluated the role of maintenance therapy, likely because of access problems. Randomized multicenter trials are needed to evaluate the role of adjuvant topical therapy. Intracavitary therapy is a worthwhile therapeutic option for conservative noninvasive upper tract TCC with acceptable side effects. For this reason it may be included in the routine urologic armamentarium.

Antifungal therapy

Upper urinary tract fungal infections are rare and are usually associated with diabetes, chronic renal failure, long-term antibiotic usage, immunosuppressants, and terminal malignancy. Diagnosis is based on microscopic examination of urine and specific fungal culture. Histopathologic examination of fungal balls (accretions) will demonstrate the fungus. The polymerase chain reaction has been used to detect candidemia in patients with candiduria, before the culture reports are available [113, 114]. Opportunistic pathogens, such as *Candida*, *Aspergillus*, *Mucor*, *Cryptococcus*, and *Histoplasma*, in particular are known to infect the kidneys in predisposed individuals with serious complications. These infections are often insidious and their diagnosis is usually delayed because of the coexisting illnesses [115, 116]. Renal involvement by fungi has been found to be associated with increased morbidity and mortality, particularly in cases of infections by angioinvasive fungi such as *Aspergillus* and *Mucor* [117–119].

Fungal infection may be systemic with secondary involvement of the urinary system, or it may originate in the urinary tract and then disseminate hematogenously. The use of an indwelling urethral catheter and administration of multiple antibiotics increases the risk of dissemination of urinary fungal infections [120]. These infections of the urinary tract must be diagnosed quickly and treated aggressively. If these infections are improperly treated, they can cause urinary obstruction through formation of fungal balls [121–123]. These fungal balls cause hydronephrosis, oliguria or even anuria, destruction of renal parenchyma, widespread dissemination of the organism, and death of the patient [124].

Percutaneous antifungal irrigation permits administration of highly toxic antifungal drugs to patients with localized infection, thereby minimizing systemic side effects [125, 126]. Systemic antifungal agents have been successfully used, but in the presence of an obstructed kidney due to extensive fungal infection, drainage of the pelvicalyceal system is mandatory to salvage the kidney. Amphotericin B and its formulations, the azoles (fluconazole, itraconazole, voriconazole, and ketoconazole), caspofungin, and flucytosine are used to treat urinary fungal infections. Schelenz and Ross reported that the intravenous antifungal drugs, such as caspofungin or amphotericin B, are useful in treating or preventing candidemia during instrumentation, such as insertion of nephrostomy tubes in cases of *Candida* pyonephrosis [2]. However, they are unlikely to lead to cure if used as the sole treatment. Conservative management should also include local drainage of pus and fungi as well as instillation of an effective antifungal agent.

The discussion below is limited to the major drugs used as topical urinary antifungals, namely fluconazole and amphotericin B. It must be kept in mind that fungal infections involving the genitourinary tract are frequently part of a multiorgan systemic disease in an immunocompromised host.

Fluconazole

Fluconazole is a triazole antifungal agent that is less toxic and more efficient than other imidazole members, and it is safe in infants and children. The drug inhibits the cytochrome P-450 enzyme responsible for conversion of lanosterol to ergosterol, the major sterol of most fungal cell membranes. Fluconazole is highly water soluble and can be administered intravenously or orally. It is cleared primarily by renal excretion, with approximately 80% of the dose excreted as unchanged drug [127]. Fluconazole administered by mouth or intravenously achieves high urine levels [128]. Generally, the drug is safe and well tolerated, even in very large doses. The most common adverse reactions are gastrointestinal disturbances.

Systemic fluconazole therapy can be effective in treating candiduria. In one series, orally administered fluconazole (100 mg twice daily for 10 days) eradicated candiduria in 19 of 20 critically ill patients, which was comparable to amphotericin B bladder irrigations [129, 130]. It is important to note that an elevated serum creatinine value is associated with a reduced rate of fungal eradication from the urine with systemic fluconazole therapy. This is likely related to lower urinary levels of fluconazole in patients with reduced renal function [131]. Therefore, in patients with renal impairment, direct irrigation may be more effective at treating candiduria.

Fluconazole has been reported as an effective antifungal bladder irrigant [132]. Percutaneous fluconazole irrigation was successfully used to treat candidiasis in nephrostomy tubes that was unresponsive to systemic intravenous treatment [126]. Fluconazole solution was used as an antifungal irrigant in 20 patients with a nephrostomy tube or suprapubic catheter who presented with two positive urine cultures for *Candida*. In 17 (85%) patients, *Candida* was eradicated from the urine by the third to sixth day of irrigation. No side effects were noted [133].

Amphotericin B

Amphotericin B was first isolated as a by-product resulting from the fermentation process of *Streptomyces nodosus* and is a member of the polyene macrolide class of antibiotics [134]. Depending on the drug concentration and susceptibility of the organism, amphotericin B may be either fungistatic or fungicidal. It binds to the sterol ergosterol that is present in the cell wall of susceptible fungi, leading to an alteration in cell wall permeability, thereby causing leakage of cell components and subsequent cell death. Oxidation-dependent amphotericin B-induced stimulation of macrophages of the host cells also may contribute to its antifungal properties [135]. Amphotericin B deoxycholate has been used in the treatment of most fungal infections, with nephrotoxicity being the most common serious chronic adverse effect[136]. Fortunately, this azotemia is usually reversible and sodium loading with intravenous saline and hydration may prevent or reduce the severity of the nephrotoxicity.

In an effort to reduce systemic side effects, new formulations of amphotericin B have been developed. These encapsulate amphotericin B in lipid vehicles which are taken up by the reticuloendothelial system concentrated in liposomes. Monocytes/macrophages in the peripheral blood are thought to take up the drug-laden liposomes and move them to the site of infection, where free active drug is thought to be released through the action of phospholipases [127].

Bladder irrigation with amphotericin B is widely used and has become a standard treatment, although it has not undergone controlled trials [134, 137–141]. Tuon *et al*. found that amphotericin B bladder irrigation (ABBI) showed a higher clearance of the candiduria 24 h after the end of therapy than fluconazole [142]. This was confirmed by fungal culture 5 days after the end of both therapies. The evaluation of ABBI using an intermittent or continuous system of delivery showed an early candiduria clearance (24 h after therapy) of 80% and 82%, respectively. The use of continuous ABBI for more than 5 days showed a better result (88% vs 78%, respectively), but this was not statistically significant. Although ABBI has been used in clinical practice, its use is not standardized, and some authors question whether amphotericin B bladder irrigations have any diagnostic or therapeutic value [143]. Others have advocated that amphotericin B no longer be used in the management of candiduria [129]. Removal of the urinary catheter, if possible, is more beneficial for the patient than instillation of bladder irrigation with amphotericin B [144].

In cases of pyonephrosis, the insertion of percutaneous nephrostomy (PCN) for direct irrigation allows urinary diversion with subsequent improvement in renal function, and enables the local administration of an antifungal drug directly to the site of infection [145]. Schelenz and Ross demonstrated the limitation of intravenous antifungal agents such as caspofungin as the sole treatment of an obstructive upper urinary tract infection due to *Candida* species [2]. In order to achieve long–term sustained cure from an obstructive pyonephrosis, pus and fungal balls should be drained and an antifungal agent such as amphotericin B deoxycholate instilled locally. An important issue in the management of pyonephrosis caused by such infections is the accumulation of pus and fungi in an obstructed space, the renal pelvices. As with other enclosed bacterial infections such as empyemas, drainage of the pus is of fundamental importance and may explain why systemic treatment with antifungals such as amphotericin B, caspofungin, or fluconazole alone have proven to be unsuccessful [126, 146]. Watson *et al*. reported percutaneous upper urinary tract drainage to be a potentially life-saving adjunct in the treatment of pyonephrosis [147]. Several case studies highlight the advantage of this maneuver in difficult cases involving obstruction due to extensive fungus. Bartone *et al*. reported on five neonates with obstructive urinary tract candidiasis in whom PCN had a major role in management [148]. In another study, eleven PCNs were placed in seven patients (two neonates and five adults), who were identified to have renal fungal infections [145]. PCN allowed prompt microbiologic diagnosis of fungal infection (*Candida albicans* in six patients, *Torulopsis glabrata* in one); urinary diversion with subsequent improvement in renal function, enabling systemic administration of the potentially toxic antifungal drugs 5-fluorocytosine and amphotericin B (four patients), local irrigation with amphotericin B (four patients), guidewire fragmentation of fungal balls (two patients); and introduction of a Simpson atherectomy device to obtain biopsy specimens from an obstructing ureteral polypoid lesion (one patient). Untreated or neglected candidiasis may progress to fungal balls or abscess formation. Sonography is commonly used as the initial imaging procedure but retrograde and antegrade pyelographies are used for biopsy, diagnosis, and treatment [149]. The advantages

of PCN in this setting include prompt drainage of the obstruction, direct access to obtain specimens from the renal pelvis to confirm the diagnosis, direct irrigation of the fungal balls with amphotericin B, and an access route for fragmentation of fungal balls by guidewire manipulation [145]. Placement of PCN with antegrade amphotericin B irrigation, coupled with systemic antifungal therapy, is the mainstay of treatment for pyonephrosis.

Streptokinase has also been used in conjunction with amphotericin B in the treatment of pyonephrosis. Hutton reported a problematic case of a very low birthweight infant with obstructing ureteropelvic junction fungal balls that were refractory to standard measures of adequate PCN drainage, pelvic irrigation with amphotericin B, and systemic antifungal treatment [150]. In an attempt to avoid potentially difficult open surgery, the author used streptokinase solution (3000 IU/mL) for irrigation. This was successful in clearing the fungal balls, relieving obstruction, and rendering the urine sterile, and highlights the potential role for streptokinase in cases of renal candidiasis refractory to current treatment protocols.

The role of antifungal agents for upper tract fungal infections will require ongoing investigation. However, the relative rarity of this condition may preclude randomized trials. In cases of pyonephrosis the most reported approaches would include placement of a nephrostomy tube and local instillation of an antifungal agent such as amphotericin B. The advantage of topical intracavitary treatment is that highly toxic medications can be delivered to the site of infection rather than systemically, which can minimize potential side effects.

Conclusions

Percutaneous therapy delivers medications or chemotherapeutics directly into the collecting system and can be highly effective at targeting the pathology. Direst therapy allows high local concentrations to be delivered while avoiding potential systemic complications. Stone dissolution through chemolysis remains an option for urologists even in the advent of more sophisticated modalities in the treatment of urolithiasis. Direct chemolysis is most useful for cystine and struvite stones. Chemolysis is also appropriate for the treatment of uric acid stones when medical therapy is not feasible, e.g. in a patient who is noncompliant or cannot tolerate oral sodium or potassium salts. There is no clinically useful irrigant for dissolving calcium oxalate calculi. Chemolytic solutions may be used as primary therapy or as adjuncts to either ESWL or PCNL.

Intracavitary immunotherapy/chemotherapy is a useful adjuvant therapy post endoscopic management of noninvasive upper tract TCC with acceptable side effects but no individual study has shown statistical improvement in terms of survival or recurrence.

Percutaneous instillation of topical antifungal agents such as amphoteracin B permits administration of highly toxic antifungal drugs to patients with localized infection, thereby minimizing systemic side effects.

CHAPTER 27
Percutaneous Treatment of Ureteropelvic Junction Obstruction

Paul J. Van Cangh
Department of Surgery Urology, Université catholique de Louvain, Cliniques Universitaires Saint Luc, Brussels, Belgium

Introduction

Percutaneous endopyelotomy was one of the first minimally invasive surgical procedures to address a reconstructive operation. In ureteropelvic junction obstruction (UPJO), the ultimate goal remains the relief of the obstruction in order to preserve renal function, with minimal morbidity. Percutaneous endopyelotomy rapidly gained acceptance and became widely acclaimed as a new gold standard in the management of UPJO, replacing open pyeloplasty [1].

However, being totally *endo*scopic, endopyelotomy can only address intrinsic factors of obstruction; extrinsic causes cannot be corrected. In UPJO, the renal pelvis is usually dilated or redundant. Classically the volume should be reduced by resecting part of the wall, but this will not be possible with a purely endoscopic procedure, neither redundancy of the renal pelvis. This probably explains its inferior success rate compared to pyeloplasty, especially when it is applied without selection [2–5]. Similarly to many pioneering techniques, it has been superseded by newer techniques and is now less often performed (see Patient selection below) [6–8]. It nevertheless retains its status as a landmark procedure, and could be regarded as one of the first natural orifice transluminal endoscopic surgeries (NOTES) to be routinely performed [7].

Preoperative management

Preoperative evaluation of UPJO is mandatory, with a view to documenting the following critical prognostic factors: the stricture (length, nature, and degree), the involved renoureteral unit (individual renal function, degree of hydronephrosis, remaining ureter), the presence of extrinsic factors (crossing vessels, bands), and the patient themselves (Table 27.1).

Preoperative drainage

Preoperative decompression of the collecting system is advisable in totally obstructed cases, in case of active infection, or when there is a need to evaluate the function of the kidney. Tubular function recuperates in 10–15 days; glomerular function improves more slowly (over up to 3 months). Despite its potential associated morbidity, we favor a small nephrostomy tube inserted under local anesthesia rather than a double-J stent, which commonly induces an inflammatory reaction at the UPJ that may later interfere with healing.

Antegrade endopyelotomy

Percutaneous endopyelotomy (Figure 27.1)

A retrograde open-end ureteral catheter is inserted and advanced through the UPJ. If this maneuver fails, the endoscopic route should be abandoned, since further attempts to localize an impassable UPJ usually are unsuccessful, and an unguided incision is dangerous and may result in total separation of the ureter.

Percutaneous endopyelotomy can be performed with the patient already in the prone position using a flexible cystoscope; otherwise the patient is repositioned on the

table as for a classical percutaneous procedure, and a posterior calyx is punctured and catheterized. A middle or superior calyx should be selected to secure an adequate working angle on the UPJ. The tract is dilated and the nephroscope is introduced. Secondary calculi are extracted at this stage. The UPJ is easily identified by the protruding retrograde ureteral catheter and a second guidewire is introduced from above and down into the ureter (Figure 27.1A). The best orientation of the incision is still a matter of debate; we prefer to make the incision posterolaterally through the entire thickness of the pelvic wall, the UPJ, and the narrow portion of the proximal ureter, and as far down as necessary to visualize a normal caliber lumen, essentially performing an endoureteropyelotomy. A significant advantage of the direct percutaneous approach is the possibility of careful visual inspection of the pelvic wall, looking for pulsation transmitted from significant adjacent crossing vessels.

The second guidewire is advantageous to straighten and stiffen the ureter to be incised: the cold knife is railroaded on the track (Figure 27.1B and C). The specific characteristics of the knife (straight or hooked knife, scissors, etc. have little importance; equal success has been obtained with laser or electric incision (aggressive coagulation is unwarranted). When the exact length of the abnormal ureter is in doubt, a dilation balloon is inserted over the second guidewire and is inflated with contrast under fluoroscopic control, care being taken to correct any residual or additional narrowed areas (Figure 27.1D).

Prolonged stenting and drainage are deemed essential, although their exact duration is still a matter of controversy. A convenient drainage system consists of a 14/7 double-J stent straddling the incised UPJ; other drainage techniques can be used successfully, provided that extravasation is minimal and drainage is adequate. We usually leave a small nephrostomy tube in place for a few days. The internal stent is removed under local anesthesia in the outpatient clinic after 6 weeks [1, 9, 10].

Invagination technique (Figure 27.2)

A safe UPJ incision may be facilitated by the modified technique described by Gelet of Lyon, France. Instead of using a simple open-ended ureteral catheter for the initial retrograde UPJ catheterization, a dilation balloon is used and inflated below the UPJ (Figure 27.2A). After percutaneous access has been obtained, the inflated balloon is grasped from above and pulled inside the renal pelvis, invaginating the UPJ and proximal ureter (Figure 27.2B). Using the holmium laser or a small electrocautery electrode, the double tissue layer (pelvis and ureter) is incised from inside the renal pelvis, down to the plastic balloon (Figure 27.2C). If residual or additional narrowing is suspected, the balloon is reinflated on its way out to calibrate the ureter. When the balloon is deflated and removed from below, spontaneous reduction of the invagination occurs. Drainage and stenting are as in the procedure described above.

The invagination technique allows easier incision of the UPJ as the tissue is stabilized on the dilated balloon. It also reduces the risk of damaging crossing vessels, although such complications have occurred [11].

Endopyeloplasty

This ingenious procedure is a combination of endopyelotomy and pyeloplasty. Using a custom-made suturing device, a standard vertical endopyelotomy incision is sutured transversely (Heinecke–Miculikz principle). Its primary aim is healing of the endopyelotomy incision by accurate suturing, minimizing fibrosis by avoiding urinary extravasation. Preliminary results for this non-dismembered procedure appear promising. A totally dismembered procedure using the same suturing technique has been investigated. Unfortunately, the original series has not been duplicated, and to our knowledge endopyeloplasty is rarely performed [12, 13].

Retrograde endopyelotomy

In order to further reduce the morbidity of the procedure, purely retrograde approaches have been devised. They share the advantage of avoiding a percutaneous nephrostomy, but they do not allow careful regional inspection for pulsation of crossing vessels, or the direct visual control necessary for an exact incision [10].

Ureterorenoscopic approach

A small caliber ureterorenoscope is advanced up to the level of the UPJ and a posterolateral incision is performed under direct vision. The procedure is

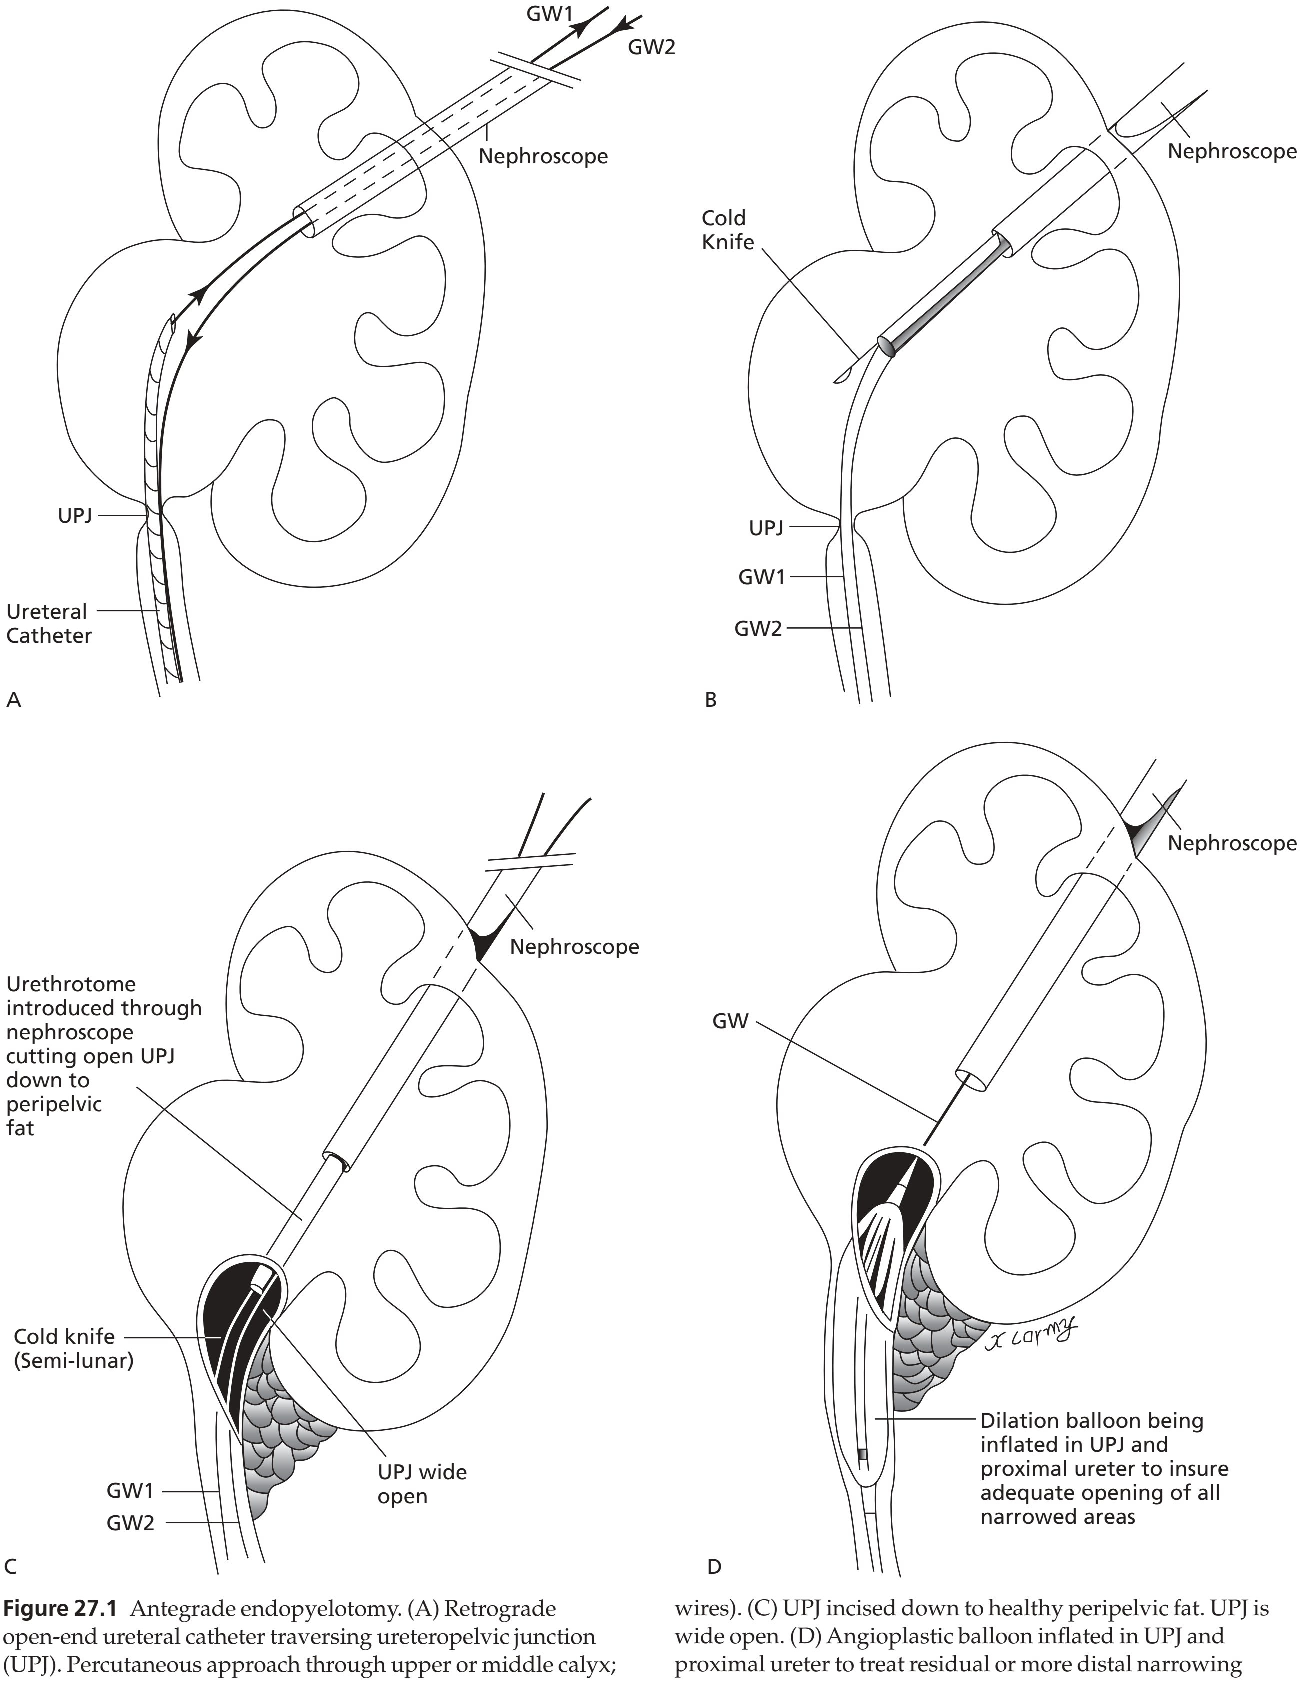

Figure 27.1 Antegrade endopyelotomy. (A) Retrograde open-end ureteral catheter traversing ureteropelvic junction (UPJ). Percutaneous approach through upper or middle calyx; second guidewire (GW) from above, down the ureter. (B) Knife through nephroscope (cutting blade railroaded by the two wires). (C) UPJ incised down to healthy peripelvic fat. UPJ is wide open. (D) Angioplastic balloon inflated in UPJ and proximal ureter to treat residual or more distal narrowing (reproduced from Van Cangh and Nesa. Endoureteropyelotomy. In: *Atlas Urol Clin North Am* 1996;4(1)).

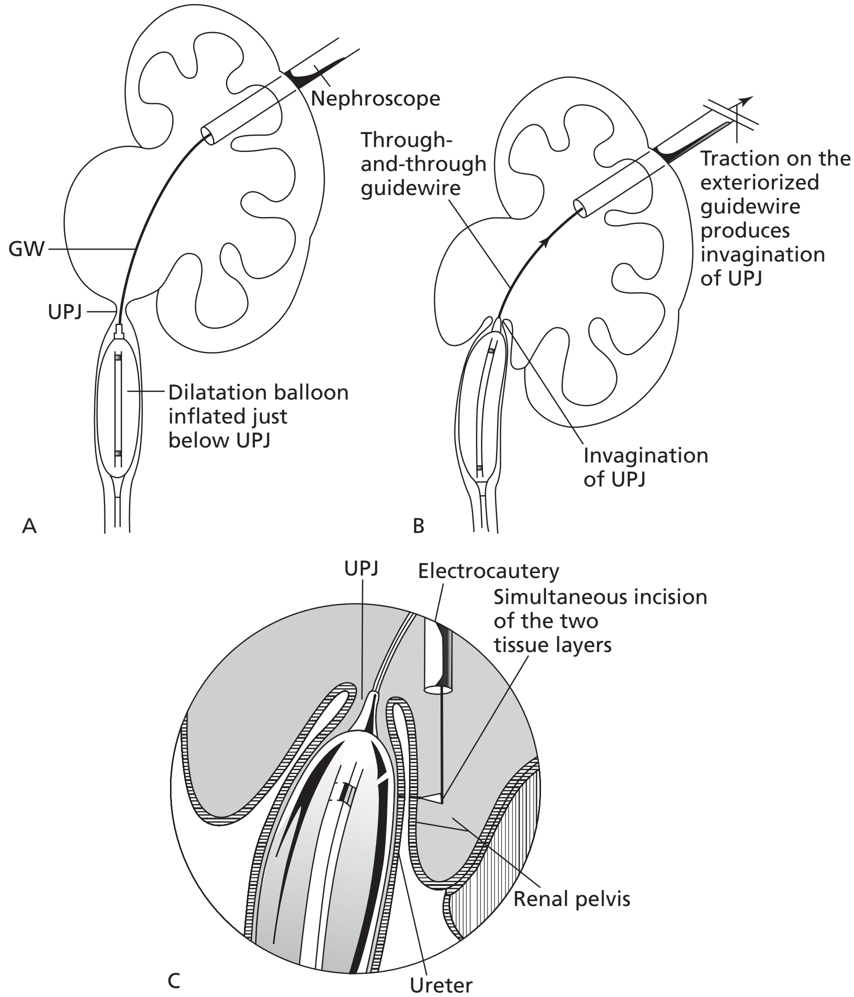

Figure 27.2 Invagination technique. (A) Dilation balloon inserted and inflated below ureteropelvic junction (UPJ). (B) Cranial traction on the exteriorized wire invaginates ureter into renal pelvis. (C) Close–up view of invaginated UPJ: laser or electrocautery incision of the double tissue layer, GW, guidewire (reproduced from Van Cangh and Nesa. Endoureteropyelotomy. In: *Atlas Urol Clin North Am* 1996;4(1)).

facilitated by the preliminary insertion of a double -J stent, which then remains in place for 8–10 days; this maneuver however, adds to the complexity of this technically difficult procedure, especially in muscular male patients. Most authors recommend the use of the flexible ureterorenoscope combined with the holmium laser.

Balloon dilation and rupture ("endoburst")

A retrograde ureteropyelogram delineates the upper collecting system. An angioplasty balloon is inserted over a guidewire and positioned across the UPJ under fluoroscopic control. The balloon is inflated until wasting completely disappears. Several inflation/deflection cycles are recommended in order to ensure that no residual narrowing remains. An endopyelotomy stent is inserted over the initial guidewire. With few exceptions, long-term success with this technique has been inferior to that with incisional techniques.

Balloon electrocautery incision: Acucise® endopyelotomy

The Acucise device is a 6F catheter driving a 10/24F low-pressure balloon fitted with an electrosurgical wire active over the 3-cm expendable portion of the balloon. The operative technique is similar to the one described immediately above, except that the UPJ is not forcefully disrupted but cleanly cut by the electrosurgical wire that is activated during inflation of the balloon. Extravasation of contrast indicates that the incision has been completed. If there is doubt, flexible ureteroscopy and additional electrosurgical or laser incision under direct vision are recommended. The technique is safe and reliable, especially when the surrounding vascular anatomy of the UPJ has been ascertained by an appropriate imaging study [14].

Laparoscopic pyeloplasty

Laparoscopic pyeloplasty combines the advantages of minimally invasive surgery (reduced morbidity) and of

Table 27.2 Therapeutic options for ureteropelvic junction obstruction.

Open surgery

Endopyeloplasty	Nondismembered Dismembered (experimental)
Laparoscopic ± robotically assisted	Intraperitoneal Extraperitoneal (Nephrectomy)

open surgery (possibility to correct anatomic factors such as extrinsic obstruction, crossing vessels, and renal pelvis redundancy), and for many has become the new gold standard. Both intraperitoneal and extraperitoneal approaches have been successful in achieving this goal. The recent advance in robotically-assisted procedures, albeit still costly, has increased the interest in this approach, by facilitating the anastomosis. Nevertheless, laparoscopic pyeloplasty remains a difficult procedure, requiring considerable expertise; it is difficult to learn and to teach [7, 15].

Prognostic factors, patient selection, and results (Table 27.2)

Results of endopyelotomy fall somewhat short of contemporary pyeloplasty (67–95% vs 95–100%) [3, 5]. As most endopyelotomy series using different techniques report approximately the same results, it is likely that selection criteria play a major role. Risk factors have been identified: the presence of vessels directly crossing the UPJ stands out as a major prognostic factor of outcome; the degree of hydronephrosis, type of obstruction, and renal function also play a role, although these are of lesser importance. Long avascular strictures and major alteration of renal function clearly contraindicate the procedure.

In our view, now commonly shared but still debated, the presence of significant crossing vessels should be ascertained preoperatively as it significantly influences the outcome. Modern imaging techniques, such as spiral computed tomography (CT), color Doppler, and endoluminal ultrasonography, have replaced the older more invasive procedures. When a significant crossing vessel has been documented, a classical endopyelotomy is likely to provide inferior results, especially in the presence of a large renal pelvis. When a small artery or a venous channel is encountered, consideration can be given to transection of the crossing vessel [9, 10]. If a major vessel is present, an alternative treatment such as open or laparoscopic pyeloplasty is preferable. When renal function is poor (<10%), laparoscopic nephrectomy is the first choice.

Today, the major indications for percutaneous endopyelotomy are the combined treatment of UPJO and concomitant pathology, the most common being secondary renal calculi and secondary UPJO [8]. In addition, several centers with expertise in the procedure continue to recommend the operation in carefully selected patients with primary UPJO.

Conclusions

Percutaneous endopyelotomy stands out as a landmark procedure, opening the way to reconstructive NOTES procedures. Like the majority of pioneering techniques, it has now been superseded by newer developments; it nevertheless retains specific indications, such as secondary UPJO and combined treatment of UPJO and associated anomalies.

CHAPTER 28

Percutaneous Management of Upper Urinary Tract Transitional Cell Carcinoma

Jonathan J. Rhee & Thomas W. Jarrett

Department of Urology, The George Washington University, Washington, DC, USA

Introduction

Transitional cell carcinoma (TCC) of the upper urinary tract accounts for approximately 5% of all urothelial carcinoma. Historically, open nephroureterectomy with bladder cuff excision has been the gold standard for treatment of upper urinary tract TCC. With the advent of minimally invasive surgery and laparoscopic procedures, patients have benefitted from smaller incision, shorter hospital stay, reduced pain, and reduced blood loss. Laparoscopic nephroureterectomy has been demonstrated to be feasible with oncologic outcomes that are comparable to open nephroureterectomy [1–3]. However, laparoscopic nephroureterectomy with bladder cuff excision still is an extirpative oncologic surgery in which the renal unit is not spared.

The need for renal preservation in a certain population of patients with upper urinary tract TCC has been recognized, and the endourologic (percutaneous and ureteroscopic) approaches have been employed since the 1980s [4–6]. Tremendous advances in endourologic management of upper urinary tract TCC have been made possible due to modern technology. In particular, modern flexible ureteroscopes provide greater deflection safely to navigate throughout the collecting system, and thoroughly to inspect each calyx for tumor [7–9]. When tumors are found, they are effectively treated with cautery or laser. Current endourologic management for upper urinary tract TCC has been shown to be feasible and a reasonable treatment option without significant compromise of survival of patients when stringent follow-up is planned [10–14].

Patient selection

Nephron-sparing surgery for upper urinary tract TCC emerged from the need to treat patients who would otherwise be anephric and require dialysis under the gold standard surgical approach. For instance, patients with anatomic or functional solitary kidney, renal insufficiency, and bilateral upper urinary tract TCC under the gold standard approach would require dialysis. Moreover, patients with multiple comorbidities often cannot tolerate prolonged general anesthesia and they are precluded from undergoing radical extirpative surgery. The indications for nephron-sparing surgery for upper urinary tract TCC are listed in Table 28.1.

As mentioned, modern flexible ureteroscopes give access to inspect the entire renal collecting system in a retrograde fashion with great success. Since this is accomplished with great accuracy, nephron-sparing endoscopic treatment options have been expanded to include patients with normal contralateral kidney. Patients with low-grade, low-stage tumor of size less than 2 cm that is completely visible and demonstrates no evidence of extension within the ureter or the kidney parenchyma on computed tomography (CT) scan have the option to undergo retrograde endourologic treatment. The results have been acceptable with proper follow-up in these cohorts [14–17]. Thus, the ideal patient for endoscopic management, using the retrograde or percutaneous approach, of upper urinary tract TCC is one with a low-grade and -stage tumor.

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Table 28.1 Absolute indications for nephron-sparing surgery for upper transitional cell carcinoma (TCC).

Renal insufficiency
Bilateral upper tract TCC
Multiple comorbidities

Tissue sampling

It is imperative to have accurate diagnoses of the grade and stage of upper urinary tract TCC because these factors influence recurrence, progression, and survival. For example, the recurrence rate for a high-grade TCC is significantly higher than for a low-grade TCC of the upper urinary tract [4]. Similarly, the stage of tumor influences the rate of progression. Superficial lesions (Ta) have a progression rate of 5%, which is much lower than the progression rates of 21% and 50% for T1 and T2 lesions, respectively [18]. Therefore, the higher grade and stage tumors require much more stringent follow-up protocols. Five-year survival rates are much higher for patients with low- -stage upper urinary tract TCC [6].

Percutaneous versus ureteroscopic management

Ureteroscopic treatment can be preferred over the percutaneous approach because a closed system is maintained and this eliminates the concern for percutaneous tract implantation. However, concern for tumor spillage exists when perforation occurs during retrograde ureteroscopic treatment. Small tumors that are easily accessed are ideal for ureteroscopic treatment since the risk of perforation associated with ureteroscopy is much lower.

There are instances when it is more advantageous to manage upper urinary tract TCC percutaneously rather than ureteroscopically,, especially in the setting of large tumors or tumors located in the lower pole calyx. Percutaneous access to the kidney provides versatility by allowing larger scopes and instruments into the upper urinary tract, which enhances the ability to ablate the tumor. Even with the superior ability to deflect, the lower pole is often difficult to access with a flexible ureteroscope when a laser fiber or bugbee electrode is passed through the working port. Moreover, the irrigation through the flexible ureteroscope becomes limited, and even slight bleeding often obscures visualization when ablating tumor with either laser fiber or bugbee electrodes.

Patients with a history of bladder cancer who have undergone radical cystectomy with urinary diversion are difficult to manage as well. The retrograde approach to inspect the upper urinary tract in urinary diversion is a challenge, especially "Bricker type," end-to-side ureteroenteric anastomosis. These patients require the percutaneous approach to obtain access into the upper urinary tract [19]. The "Wallace type" end-to-end ureteroenteric anastomosis may allow slightly easier access ureteroscopically, but this is still challenging and a percutaneous approach is usually required [20].

The percutaneous approach offers advantages over ureteroscopic treatment for reasons other than the limitations of flexible ureteroscopy, as mentioned briefly above. One of the major benefits of percutaneous treatment is that nephroscopes and resectoscopes are much larger than ureteroscopes, and therefore provide superior visualization from the optical standpoint. Irrigation flows much more freely and maximizes visualization. Larger working channels allow larger instruments to pass, in turn providing much better tissue sampling, and hence improving staging capabilities. Large tumors are ablated much more efficiently and operative time is reduced. A percutaneous nephrostomy tube is left in place at completion of resection. It allows proper drainage and serves to achieve hemostasis. It also allows subsequent re-examination or serves as percutaneous access if instillation of intracavitary agents into the upper urinary tract is considered. Although percutaneous management may pose more risks than ureterscopic management, there are circumstances where treating upper urinary tract TCC percutaneously are much more advantageous [21, 22].

Puncture selection

The principles of obtaining access for percutaneous nephrolithotomy apply for percutaneous treatment of upper urinary tract TCC. As the puncture site moves more medially, the risk of injury to the renal vessels increases and direct puncture into the renal pelvis may occur. The latter should be avoided since the posterior branch of the renal artery is in close proximity and can cause significant bleeding [23]. In addition, the renal pelvis does not provide stability for the access sheath since there is no parenchymal support, and this may result in a large laceration when manipulating the scope during resection.

The location of percutaneous access is dictated by the location of the tumor. Tumors located in the peripheral calyces are best approached by placing the access in direct line with the tumor and not directly on the tumor. Tumors located in the proximal ureter or renal pelvis may be approached either from the middle or upper calyx to access the ureteropelvic junction (UPJ) in a straight path (Figure 28.1) [24]. More than one access may be required when large tumors are located in different calyces.

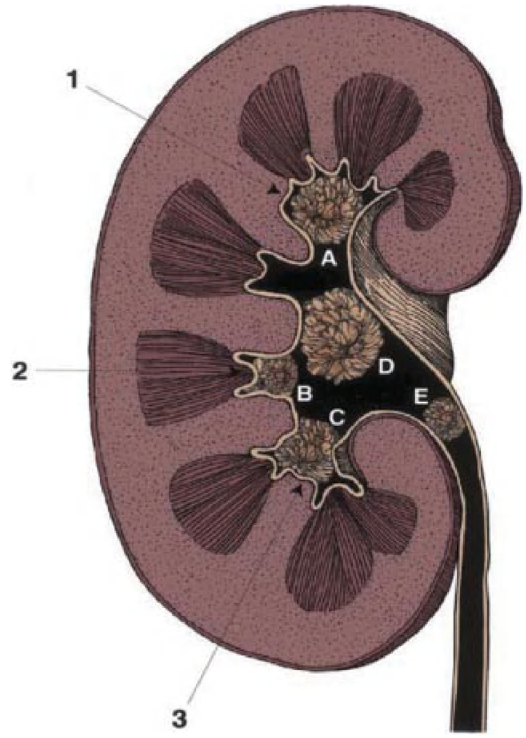

Figure 28.1 Nephrostomy track puncture site. Tumors in peripheral calyces (A–C) are best approached by direct puncture as far distally in the calyx as possible. Tumors in the renal pelvis (D) are upper ureter (E) are best approached by puncture to an upper (1) or middle (2) calyx, which allows the scope to be maneuvered in the renal pelvis and down the ureter. Tumors in the lower calyx are approached by lower calyx puncture (3) (reproduced from Sagalowsky & Jarrett [24], with permission).

Techniques of resection

After gaining percutaneous access, there are different methods to achieve resection or ablation of upper urinary tract TCC (Figure 28.2) [24]. Resection of tumor can be achieved with monopolar or bipolar loop electrodes, or tumors can be ablated with lasers.

A large access sheath allows a standard resectoscope with cutting loop to be introduced into the upper urinary tract. The access sheath maintains a low pressure system with irrigation through the scope. With the standard monopolar cutting loop, the tumor is electrosurgically resected to the base and the specimen is extracted (Figure 28.2A). This technique works well for papillary tumors on a narrow stalk (Figure 28.3). Broad-based tumors may cause excessive bleeding and are best approached with resection of the laser therapy. Hemostasis is easily accomplished at the base of the resection by electrocautery. In addition to resection, electrovaporization can be accomplished with a 200-W pure cutting current of the monopolar device [25]. The increased current causes immediate cell death by direct vaporization and the underlying tissue is desiccated and coagulated [15].

Another type of resection device is the bipolar loop electrode. This device also has been utilized for treating benign prostatic hyperplasia. The irrigation medium used for bipolar electrodes is normal saline, which minimizes the change in serum sodium and other electrolyte abnormalities during resection. When water is used as an irrigation medium, hyponatremia and other electrolyte abnormalities may occur [26, 27]. With the bipolar loop resection, deep tissue sampling is possible, just as with the standard monopolar loop [28]. Hemostasis is achieved in a manner similar to that with the monopolar loop.

Tumor ablation can also be accomplished using lasers (Figure 28.2B–D). The neodymium (Nd):YAG and holmium (Ho):YAG are two well-established laser systems in urology. The induced effects on soft tissue vary between coagulation, vaporization, and incision, depending on the contact versus noncontact mode. Both lasers on contact mode have the capability to vaporize or incise tissue.

The Nd:YAG laser is well-suited and widely used for bladder tumors and upper urinary tract TCC. The noncontact mode of this laser will coagulate the tumor. The Nd:YAG laser fiber is placed in close approximation to tissue, but not in direct contact, and the laser is activated at around 20–30 W to coagulate the tissue [6]. The distal fiber tip should be directed tangentially in a noncontact mode until the tissue coagulates. This laser penetrates tissue to a depth of approximately 5–6 mm, so bulky tumors are ablated much more efficiently. Due to the depth of penetration, the Nd:YAG laser should never be used circumferentially in the ureter, as it may cause ureteral stricture [29]. As the tissue coagulates, the coagulated portion of the tumor is removed with forceps, which exposes deeper portions of the tumor that require further coagulation. The coagulation and ablation is repeated until the base of the tumor is exposed.

In contrast, the Ho:YAG laser must be in direct contact with the tumor to coagulate, vaporize, and incise tissue. It has a penetrating tissue depth of 0.5 mm. The shallow depth of penetration allows the tissue ablation to be focused and circumferential lesions to be treated. However, it will not coagulate large vessels [30, 31]. Thermal energy generated by the Ho:YAG laser is highly absorbable by water so that the heat disperses very rapidly through the irrigation medium. This physical property results in minimal thermal damage to the surrounding tissue [32]. However, one of the drawbacks of Ho:YAG laser is that the tumor adheres to the tip of the fiber during ablation, which often decreases visualization and ablation capacity. This can be minimized by cleaning the fiber tip but the cleaning process adds to

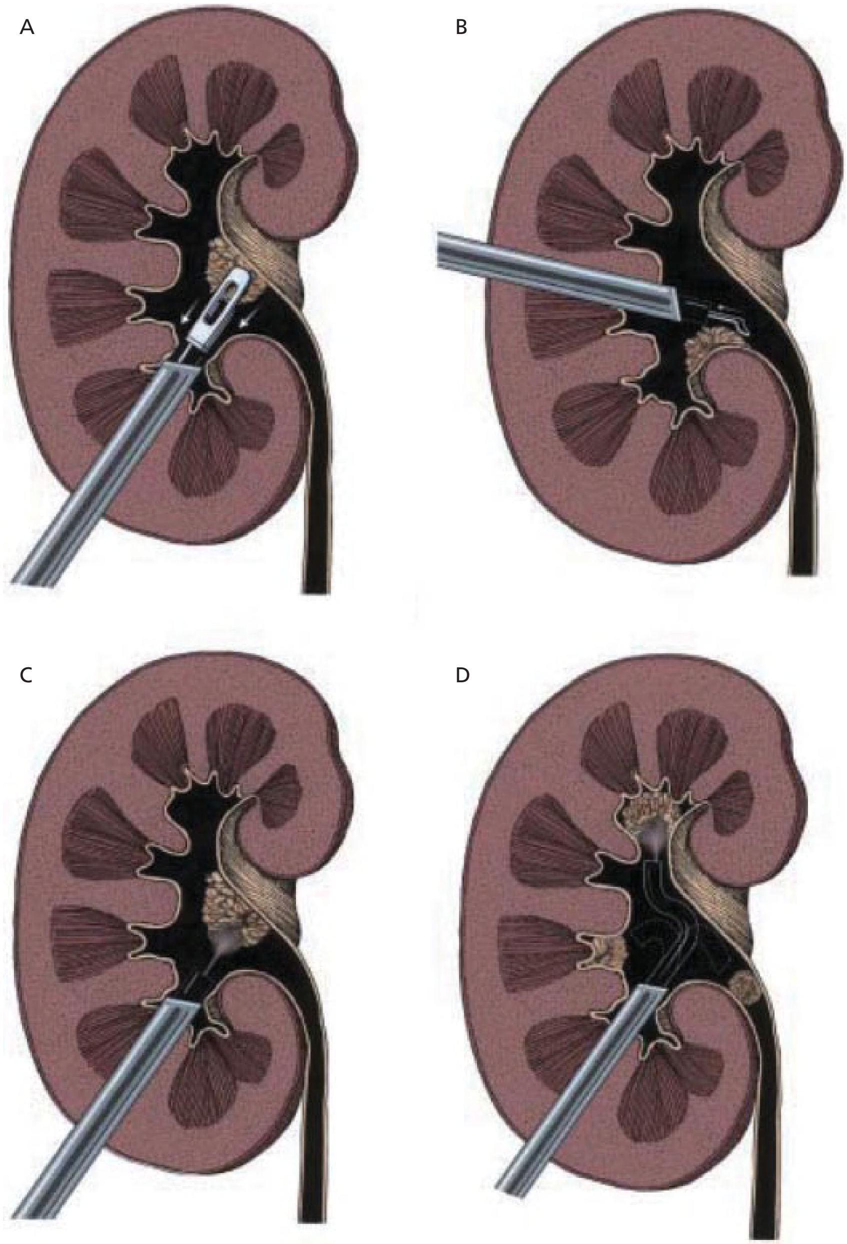

Figure 28.2 Resection of upper urinary tract transitional cell carcinoma. (A) The tumor is identified and debulked by forceps to its base. The base is sampled and sent separately for evaluation. (B) With the use of a standard resectoscope, the tumor is identified and resected to its base. Special care should be taken to avoid resection into major renal vasculature. The tumor is sampled for diagnostic purposes and treated by holmium or neodymium laser sources. This can be done through a standard nephroscope (C) or with a flexible cytoscope (D) (reproduced from Sagalowsky & Jarrett [24], with permission).

operative time. A gentle flow of irrigation is used to clear tumor debris during the ablative treatment.

A combination of the two lasers can be used during one procedure. The Nd:YAG laser can coagulate the majority of the volume of a large tumor, and then the Ho:YAG laser can be employed to ablate the remaining tumor tissue [33]. Particular attention should be given to ensure that the fiber tip is visible in front of the scope at all times.

Complications

Complications from percutaneous treatment of upper urinary tract TCC are much more common than from

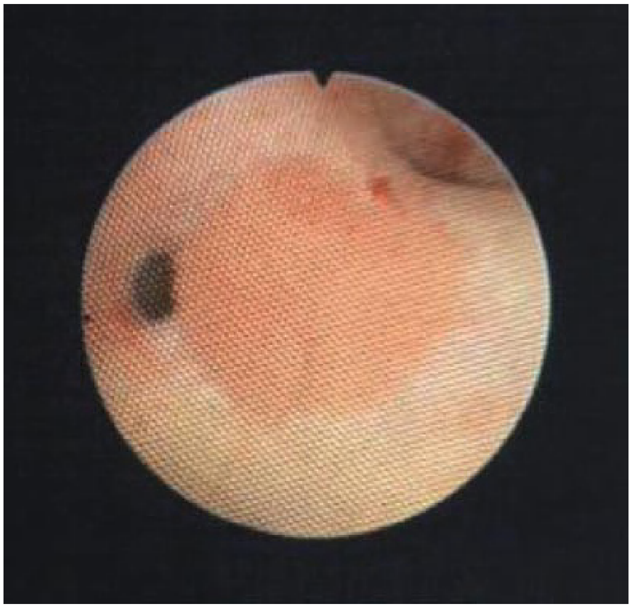

Figure 28.3 Papillary tumor.

the ureteroscopic approach: hemorrhage, urinary tract perforation, UPJ obstruction (UPJO), and pleural, bowel, and spleen injury.

The most common complication due to percutaneous treatment is hemorrhage. Transfusion requirements can range from 20% to 50% [34, 35]. The amount of bleeding is directly related to the grade and stage of the tumor because high-grade and -stage tumors require deeper resection, which may lead to increased postoperative bleeding [36]. Risks for postoperative bleeding also increase with multiple punctures and access, medial puncture, abnormal renal anatomy, and patients on anticoagulants. Blood loss during the procedure is usually managed conservatively with large-bore nephrostomy tube placement to tamponade bleeding from the percutaneous tract, bed rest, and blood transfusion; however, refractory bleeding may require angiographic embolization.

Delayed bleeding may occur from pseudoaneurysm or arteriovenous fistula formation. Pseudoaneurysm results from the weakening of the vessel wall, which is caused by the dilation of the percutaneous tract. This leads to intermittent bleeding into the collecting system, and patients usually present with hematuria with or without clots. Arteriovenous fistula results when injury near the proximal artery and vein occurs, which allows blood to flow from the high to low pressure system. Delayed bleeding is a serious complication that needs immediate attention. If not treated immediately with angiographic embolization, it can lead to a catastrophic event.

Urinary tract perforation can occur during resection or when obtaining access. When the injury is unrecognized during the resection, the perforation can inadvertently get larger, and it can lead to a massive hydroabdomen [37]. One method to minimize perforation is the use of a large access sheath to create a path of low resistance through which irrigant can exit freely. This reduces the pressure within the collecting system while allowing good visualization. Once the perforation is recognized, the procedure should be stopped and maximal drainage of the upper urinary tract should be accomplished with an internal stent and percutaneous nephrostomy tube.

UPJO can occur from overzealous cautery and/or resection, especially when cautery is performed circumferentially. Aggressive maneuvering of the scope can cause mucosal abrasion and edema, obstructing the UPJ, and can also disrupt the UPJ. Surgeons should take particular care when using larger scopes in order to minimize trauma to the UPJ.

Pleural injury can occur, especially when the access is obtained supracostally. Since the pleural space extends inferiorly to the 11th or 12th rib posteriorly, the violation of the pleural cavity is a well-known complication [38]. Pleural injury is recognized at the end of the procedure by intraoperative fluoroscopy, and usually the hydrothorax or pneumothorax can be seen. When this is confirmed, it can be managed with postoperative insertion of a chest tube or thoracentesis [39]. A small chest tube (10F) can be placed intraoperatively under fluoroscopic guidance while a patient is still under general anesthesia. A percutaneous renal access needle is placed perpendicular to one of the intercostal spaces along the posterior axillary line. The Seldinger technique is performed to place a small chest tube into the thoracic cavity [40].

Although uncommon, injury to the adjacent organs such as the bowel or spleen can occur. Colonic perforation can occur in patients with anatomic renal abnormalities, such as horseshoe kidney, renal fusion, and renal ectopia. Rare anatomic abnormalities, such as a retrorenal colon, can also predispose patients to colonic injury. In general, the risk of bowel perforation is increased with more lateral puncture. If the bowel perforation is contained in the extraperitoneum, it is treated conservatively with a ureteral stent and placing a tube into the lumen of the bowel to separate the two systems. If the bowel perforation is intraperitoneal, surgical correction should be considered. Injury to the spleen may occur in patients with splenomegaly. When a spleen laceration is encountered, surgical exploration should be considered due to significant hemorrhage.

Access tract seeding is an important consideration for percutaneous procedures for upper urinary tract TCC. While rare, there have been a few reported cases of the percutaneous tract recurrence of TCC [22, 41–43]. As mentioned earlier, the use of a large access sheath

decreases the intrarenal pressure, and it may minimize tumor implantation of the percutaneous tract [6]. Most of the tract recurrences occur with high-grade TCC. However, low-grade disease can also implant and cause recurrence if tumor spills into the wound and when proper surgical technique is not maintained [44, 45]. Interestingly, tract seeding has been reported for renal cell carcinoma as well [42].

Second-look nephroscopy

Percutaneous management should incorporate the goal of complete resection. This can be achieved by second-look nephroscopy to confirm complete resection and reassess residual tumor burden. The percutaneous tract is typically maintained with a 24F nephrostomy tube, and second-look nephroscopy is performed usually within 4–7 days after the initial treatment. The main objective of a second nephroscopy should be to re-resect any residual tumor and/or fulgurate the base of tumor. A third nephroscopy can be considered 2 weeks after Bacillus Calmette-Guérin (BCG) instillation when the index of suspicion is high, and random biopsy or tumor resection may be performed again at that time [34]. However, at any time, invasive or high-grade disease should prompt nephroureterctomy with ipsilateral bladder cuff excision if the patient is able to tolerate radical extirpirative surgery or is not expected to require hemodialysis.

Intracavitary BCG, administered via percutaneous nephrostomy tube, can be considered after the second-look nephroscopy. The objective is to reduce recurrence and progression of disease. BCG is administered once weekly for 6 weeks (see below and Chapter 26).

An algorithm for percutaneous treatment of upper urinary tract TCC is depicted in Figure 28.4.

Results

The first series of percutaneous management of upper urinary tract TCC was described in patients with solitary kidney by Smith *et al*. in 1987 [45]. Since then, numerous studies have described the percutaneous management of upper urinary tract TCC (Table 28.2) [22, 34, 46–48]. As mentioned earlier, the recurrence and progression of upper urinary tract TCC depend on grade and stage of the original tumor, the two most important prognostic factors. Recurrence for low-grade tumors occur at much lower rates (18–28%) than for high-grade tumors (50%) [34, 47].

Grade 1 tumors are most often superficial tumors without submucosal invasion. Risk of metastatic disease without submucosal invasion appears to be minimal, and the recurrence rates demonstrated by Jarrett *et al*. and Clark *et al*. for low-grade tumors are 28% and 18%, respectively [34, 47]. The percutaneous resection is well tolerated and it can be repeated if upper urinary tract TCC recurs. Grade 2 tumors behave more aggressively than grade 1 tumors, with higher invasive potential that often results in understaging due to inadequate resection. There is a higher complication rate compared to that for low-grade tumors, resulting from the more aggressive resection, since grade 2 tumors tend to invade deeper than the mucosa. Grade 3 tumors behave very aggressively, with most found to invade into or beyond the submucosa. The recurrence rate for grade

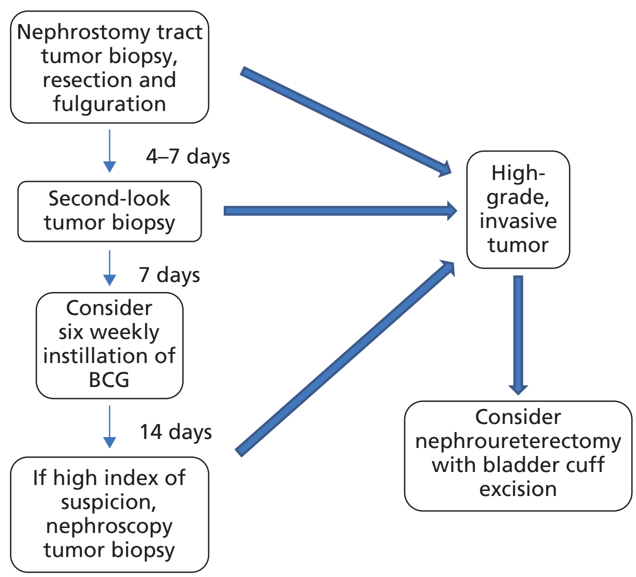

Figure 28.4 Percutaneous management of the upper tract transitional cell carcinoma.

Table 28.2 Results of percutaneous approach for upper urinary tract transitional cell carcinoma.

Series	Number of patients	Recurrences (%)	Nephroureterectomies (%)	Duration of study (months)
Jarrett *et al*. 1995 [34]	36	10 (28)	15 (42)	9–111
Patel *et al*. 1996 [46]	28	6 (23)	6 (23)	1–100
Clark *et al*. 1999 [47]	18	6 (33)	2 (11)	2–76
Palou *et al*. 2004 [48]	34	14 (41)	11 (25)	Mean 51
Roupret *et al*. 2007 [22]	24	8 (32)	(20)	Mean 62

3 is as high as 50% [34, 47]. In their series, Jabbour *et al*. and Jarrett *et al*. demonstrated that all deaths during follow-up occurred in patients with grade 3 disease [18, 34]. Death was reported in these patients whether they had local recurrence or not, which suggests the aggressive nature of high-grade tumors with higher metastatic potential.

Patients with confirmed grade 3 disease have been considered for radical nephroureterectomy with bladder cuff excision [22, 34, 46–48], but this has not shown significant survival benefit when compared to patients who underwent percutaneous resection alone [49]. These data indicate that higher histologic grade tumor presents with more advanced disease and radical surgery may have no bearing on survival benefit. Given that survival benefit is questionable, percutaneous management may provide improved quality of life if the need for dialysis is delayed.

Percutaneous management is an option for certain cohorts of patients, particularly the elderly. Kang *et al*. reported 2- and 5-year survival rates of dialysis patients with primary upper urinary tract TCC of 74% and 43%, respectively [50], and Jager *et al*. reported 2-year survival of 51% in dialysis patients [51]. Not unexpectedly, mortality is higher among elderly dialysis patients [52]. According to the American Society of Nephrology (ASN), elderly patients in preterminal stages should receive information regarding life-expectancy before dialysis is considered [53]. Interestingly, a large cohort of elderly patients on dialysis revealed that they perceive themselves as physically inferior to the general population of the same age [54]. Heart disease, hypotension, intestinal bleeding, and amyloidosis are significant elements of dialysis in the elderly population that can dramatically affect quality of life.

Intracavitary therapy

The mainstay of intravesical treatment for superficial bladder cancer has been the use of BCG [55, 56], but other intravesical chemotherapeutic agents have been used (see below and also Chapter 26). The response rate for superficial bladder cancer has been variable depending on the intravesical chemotherapeutic agent used. To replicate the superficial bladder tumor response data from intravesical BCG treatment, the use of BCG for upper urinary tract TCC was first described by Herr in 1985 [57].

The safety of administration of BCG into the upper urinary tract is well-established [58]. Notwithstanding this fact, some have expressed concern for systemic BCG infection. Usually, patients present with high fevers, rigors, and malaise, which mimic a general infectious process. Fortunately, when patients present with fevers, they are usually caused by urinary tract infection and not systemic BCG infection [59]. Fevers should alert the urologist to the possibility of BCG sepsis. BCG sepsis has devastating sequelae and serious steps should be taken to prevent systemic BCG infection. In order to decrease the likelihood of systemic BCG infection, the percutaneous tract is allowed to mature for 1–2 weeks after resection if the patient is to be treated with BCG [49, 60]. Typically, patients have a urine culture from the percutaneous nephrostomy tube, and receive antibiotics prior to BCG instillation.

Safety measures can be practiced to minimize complications from BCG instillation into the upper urinary tract. Typically, normal saline is infused via the percutaneous nephrostomy tube, starting at a very slow rate, and gradually increasing to a rate of approximately 50 mL/h. Normal saline is continued for approximately an hour with intrapelvic pressure monitored to maintain it at less than 25 cmH_2O (Figure 28.5) [24]. At that point, the BCG is instilled under gravity via the percutaneous nephrostomy tube. The instillation should be stopped if the intrapelvic pressure increases above 25 cmH_2O or the patient complains of fever or pain. It is important to monitor the intrapelvic pressure because high pressure can lead to pyelovenous backflow of BCG, which can increase the risk of BCG sepsis. BCG is instilled once a week for 6 weeks. After the completion of six cycles of BCG, another nephroscopy is considered when the index of suspicion is high, and usually performed 2 weeks after the last cycle of BCG instillation. When tumor or abnormal mucosa is encountered, it can be biopsied and treated.

Another method of instilling BCG is using a retrograde approach. A straight ureteral catheter is placed into the renal pelvis endoscopically and BCG is instilled into the renal pelvis. This method requires that patients be admitted to hospital and observed after instillation. The instrumentation can cause significant ureteral edema, which can lead to ureteral obstruction and Gram-negative sepsis if care is not taken. Another disadvantage of this method is that patients will need endoscopic placement of a straight catheter with every instillation. To circumvent this issue, a single-J stent can be placed percutaneously via cystotomy, obviating the need for the endoscopic procedure [61].

Alternatively, a refluxing double-J stent may be placed endoscopically and intravesical BCG instilled, allowing intravesical BCG to reflux up into the renal pelvis. The amount of intravesical fluid needed to induce reflux ranges from 80 to 250 mL (median of 120 mL) [62]. Cystography is performed to confirm reflux since a double-J stent does not guarantee reflux [63].

Ureteral meatotomy can be performed to cause vesicoureteral reflux. After the double-J stent is removed, reflux is confirmed with cystography and the volume necessary to cause reflux is recorded. An

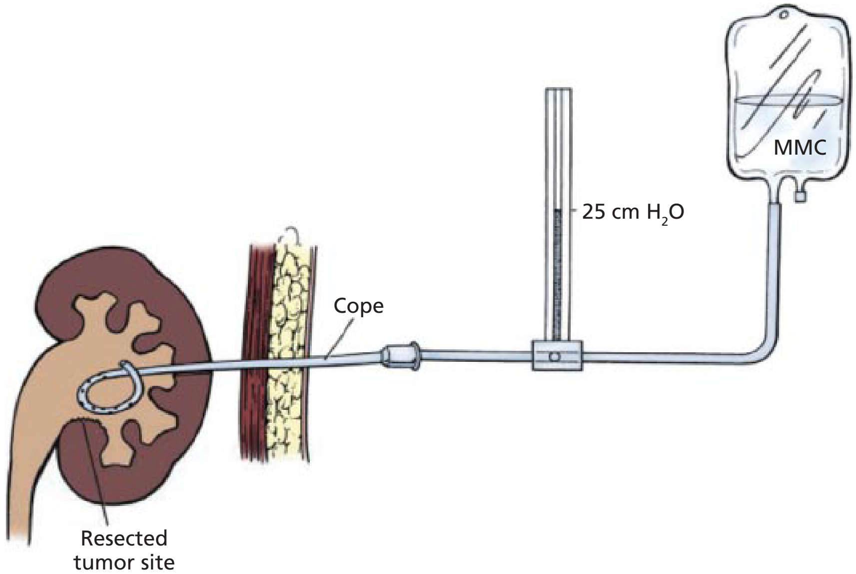

Figure 28.5 Set up for administration of topical immunotherapy or chemotherapy to the upper urinary tract through a previously placed nephrostomy tube. Therapy is instilled under gravity with a mechanism that prevents excessive intrarenal pressures. MMC, mitomycin C (reproduced from Sagalowsky & Jarrett [24], with permission).

appropriate volume of BCG can be administered intravesically [64].

Reports of the efficacy of BCG treatment for the upper urinary tract have been conflicting. However, most data show that survival benefit from intracavitary BCG therapy is inadequate [34, 47]. Hayashida *et al*. demonstrated a 50% recurrence rate, and showed 100% mortality for patients in whom TCC recurred after BCG treatment [65]. In contrast, Okubo *et al*. found some long-term benefit with tumor-free survival at a median follow-up of 46 months in their cohort [66]. Data should be interpreted very cautiously since instillation of BCG does not seem to prevent recurrence or progression of the higher-grade upper tract TCC. However, there may be some benefit for low-grade tumors and carcinoma *in situ* [67]. One major issue for advanced and/or high-grade tumors is that the BCG instillation regimen will allow these tumors to progress while the six cycles are completed. Due to the inadequate response to BCG, some advocate CT scans to monitor lymph nodes or metastatic status during the six cycles of BCG.

Other intracavitary agents that have been studied are mitomycin C and thiotepa. Keeley *et al.* instilled mitomycin C after ureteroscopic treatment in 19 patients. Eleven patients had a good response and were to tumor free during follow-up [44]. Martinez-Pineiro *et al.* observed a lower recurrence rate for patients who were treated with BCG and mitomycin C than for patients who were treated with thiotepa [11].

Unlike the intravesical BCG therapy for superficial bladder TCC, statistically significant survival benefit has not been demonstrated for upper urinary tract TCC. A randomized trial to study the efficacy of intracavitary therapy of upper urinary tract TCC is necessary.

Follow-up

Careful follow-up and evaluation of upper urinary tract TCC is crucial, and it should be performed so that recurrences are recognized and treated quickly. Any signs and symptoms should prompt further investigation. There are no set guidelines for the evaluation of percutaneously managed upper urinary tract TCC, but short-interval evaluation is strongly encouraged during the first few years after initial percutaneous resection. Patients are typically evaluated once every 3 months for a year, every 6 months for 4 years, and then annually. Iwaszko *et al*. recommend ureteroscopy once every 3 months for the first 2 years, then every 6 months for the next 2 years, and then annually [36]. The surveillance protocol should include history and physical examination, urine cytology, cystoscopy, and CT urogram or retrograde pyelogram [34]. Ureteroscopy and upper urinary tract cytology are performed on the basis of suspicion for recurrence. Upper tract imaging should include the contralateral kidney. With the advent of superior optics and smaller ureteroscopes, ureteroscopy is much more sensitive than intravenous urogram, and the tumor can be treated at the time of diagnostic ureteroscopy.

High-grade TCC has a greater tendency to recur and potential for stage migration, and it requires more vigilant follow-up with a higher index of suspicion for recurrence during evaluation.

Conclusions

The percutaneous treatment of upper urinary tract TCC is feasible and sometimes necessary for a certain group of patients. When the nephron-sparing endoscopic approach is chosen to treat upper urinary tract TCC, a proper follow-up plan is absolutely necessary. Higher grade tumors should prompt a more rigid follow-up plan, as they behave more aggressively than lower grade tumors.

CHAPTER 30
Hemorrhagic Complications Associated with Renal Surgery

Ardeshir R. Rastinehad,[1] Sero Andonian,[2] & David N. Siegel[3]

[3]Division of Vascular & Interventional Radiology, North Shore – Long Island Jewish Health System, Long Island, NY, USA

Introduction

Over the past 30 years, urologists and interventional radiologists have contributed to the evolution of complex open surgical procedures into minimally invasive techniques. For example, the anatrophic nephrolithotomy for the treatment of kidney stones (the Boyce procedure), which was once the gold standard for the treatment of staghorn calculi, has now been replaced by percutaneous nephrolithotomy (PCNL), which offers shorter operative time, lower transfusion rate, lower narcotic requirement, shorter hospital stay, faster convalescence, and lower cost [1]. Minimally invasive procedures have been expanded to include therapies for renal masses. These include laparoscopic partial nephrectomy (LPN), percutaneous tumor ablation using cryotherapy, and radiofrequency ablation. Furthermore, percutaneous biopsy of renal tissue, or needle aspiration, has become a popular tool in the diagnosis of renal masses, as per the recent American Urological Association (AUA) guidelines for small renal masses [2].

Preoperative patient preparation

Initial evaluation of the patient should include a detailed history and physical exam to elicit any signs or symptoms of bleeding dyscrasias. Further work-up as needed by hematology should be performed as an uncorrected coagulopathy is the only absolute contraindication for percutaneous renal surgery. All medications, including over-the-counter herbal supplements that could affect coagulation should be reviewed. Preoperative labs should include a prothrombin time/partial thromboplastin time (PT/PTT), international normalized ratio (INR), complete blood count, and serum electrolytes; and cross-matched blood should be available, depending on the type of case. A preoperative urine culture should be negative.

Another subset of patients who are at increased risk of hemorrhage are those with cardiac stents who are unable to discontinue their antiplatelet medication prior to surgery. It is important to have a discussion with the interventional cardiologist who placed these stents to weigh the risks and benefits of discontinuing antiplatelet agents, such as acetylsalicylic acid (Aspirin) and clopidogrel (Plavix), compared to postponing the planned procedure. These patients should be advised of increased risks of coronary events and postoperative hemorrhagic complications once antiplatelet agents are reinitiated or continued through surgery [3].

The recommendations are as follows: antiplatelet agents, such as acetylsalicylic acid and clopidogrel, should be stopped 10 days prior, warfarin 5 days prior, intravenous heparin 6 h prior, and low molecular weight heparin 24 h prior to surgery [4]. The incidence of thromboembolic events in patients who are off anticoagulation for atrial fibrillation (ischemic stroke) and recurrent deep vein thrombosis/pulmonary embolism (DVT/PE) are 4.5%/year and 7.2%/year, respectively [5]. When the daily incidence is calculated, the risks are small but tangible. Therefore, these patients should also be advised of the increased risks of thromboembolic events

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

and postoperative hemorrhagic complications that may occur once anticoagulation therapy has been reinitiated.

Risk of hemorrhage with renal procedures

Percutaneous renal biopsy

In the USA, the incidence of renal cell carcinoma (RCC) has been increasing steadily. In 2009, there were 57 760 new cases of kidney cancer and 12 980 estimated deaths from this disease [6]. The previous paradigms in urology for the treatment of renal masses did not support the use of renal biopsy, due to high false-negative rates. However, percutaneous renal tumor sampling (either with fine needle aspiration cytology or core biopsy) has become part of the algorithm for management of renal masses [2], especially in elderly patients with comorbidities. Furthermore, it is performed at the time of percutaneous renal ablative therapies to confirm the diagnosis.

Currently, the diagnosis and treatment of small renal masses has been evolving with the advent of new and improved imaging modalities as well as advances in immunohistochemical staining and molecular profiles. Historical series have estimated the incidence of immediate postbiopsy subclinical hematomas to be 91%. A recent series reports the incidence of postbiopsy hemorrhage (subcapsular and perinephric) to be lower (38.4%, 28 of 73) when 18G core needle biopsies are performed [7]. All hemorrhagic complications were managed conservatively; no embolization or blood products were required in this series [7].

Percutaneous cryotherapy/radiofrequency ablation

Numerous studies report 2- and 5-year data gathered subsequent to computed tomography (CT)-guided percutaneous ablative therapies with either cryoablation or radiofrequency ablation [8–13]. Most postablation CT/magnetic resonance imaging (MRI) scans are performed immediately after removal of the probes. Therefore, these postablation scans may not be a sensitive test for postoperative hemorrhage. Nonetheless, the incidence of acute postoperative hemorrhage ranges from 0.9% [14] to 49% [11]. This large variation is possibly due to the different authors' definitions of postoperative hemorrhage and the large time delay involved in performing postoperative scans. Cryoablation, as compared to radiofrequency ablation, has been associated with an increased risk of hemorrhage due to lack of thermal coagulation (Figure 30.1). In both the series reported by Georgiades *et al*. [11] and Hafron and Kaouk [14], patients were treated with conservative management. Georgiades *et al*. reported that 15 of 51 (29%) patients developed small asymptomatic perirenal hematomas and 10 of 51 (20%) developed large painful perirenal hematomas [11]. For patients undergoing percutaneous ablation, transfusion rates ranged from 0% to 4% and no patients required renal angioembolization [10,11].

Clayman *et al*. reported that tumor size directly correlated with incidence of bleeding. Tumors with a median size of 4.2 cm were associated with increased rates of postablation hemorrhage when compared to tumors with a median size of 2.6 cm ($P > .05$) [13]. When only a single probe is used, the rate of bleeding decreases to 0%. The use of multiple probes increases the degree of renal trauma and, hence, the incidence of bleeding complications [13].

Percutaneous nephrolithotomy

Despite the fact that percutaneous renal surgery is associated with lower morbidity, it is not without its complications [15, 16]. Lang performed a large multiinstitutional survey of patients undergoing PCNL. The overall complication rate was reported to be 26% [17]. The complication rates had a direct correlation with experience, which decreased from 61% to 3.7% with an increase in the level of experience [18].

The initial series of PCNL reported an 11% incidence of postoperative transfusions [19]. Lang, in 1987, reported the results of a survey of 62 institutions with a transfusion rate of 0.43% in patients undergoing PCNL [17]. In 2007, a study from the University of Western Ontario reported a post-PCNL transfusion or embolization incidence of 0.8% [18]. Stoller *et al*. reviewed risk factors associated with blood transfusions post PCNL and reported an association with multiple punctures, renal pelvic perforation, inexperience, preoperative anemia. and total blood loss [20].

Some authors have postulated that balloon dilators could decrease the risk of hemorrhage associated with PCNL. Recently, Wezel *et al*. compared two series of rigid dilations and balloon dilations and also performed a literature review. The authors found no difference in transfusion rates between the two techniques [21].

Laparoscopic partial nephrectomy

The majority of the literature regarding the complications of renal surgery focuses on the comparison of open to laparoscopic techniques. When evaluating the hemorrhage associated with laparoscopic renal surgery, it is important to keep it in perspective, because authors define the term "hemorrhage" in multiple ways. For example, a hemorrhage that requires a blood transfusion differs significantly from a hemorrhage that requires

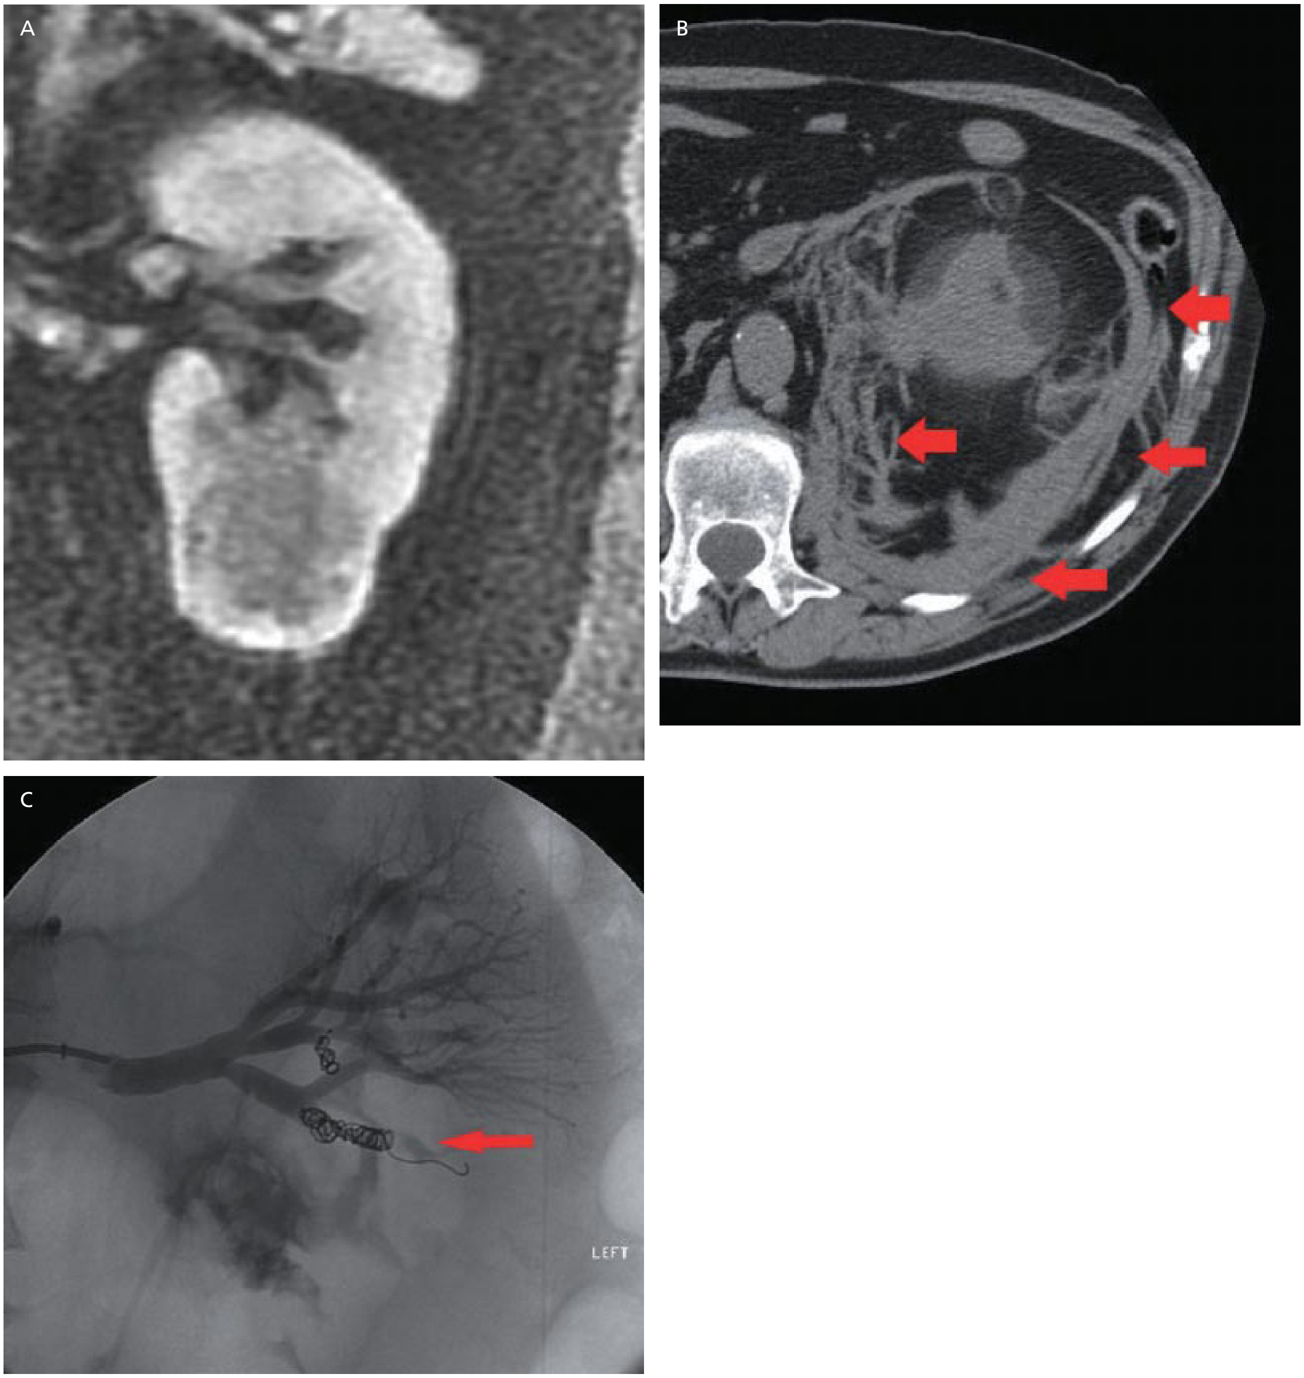

Figure 30.1 (A) Coronal reconstruction of lower pole renal mass. (B) Postprocedural CT scan of a patient with active hemorrhage after treatment of a 4-cm right lower pole renal mass with multiple cryoablation probes (arrows). (C) Postrenal angioembolization using coils (arrow).

reoperative management or embolization. Therefore, it is difficult to compare series. According to a review by Uzzo and Novick, the incidence of hemorrhage in the open series ranged from 1.4% to 7.9% [22].

An early LPN series from the Cleveland Clinic reported a 9.5% (19 of 200) perioperative incidence of hemorrhage requiring blood transfusions [23]. Patients with immediate hemorrhaging postoperatively were managed conservatively 2% (4 of 200), and delayed hemorrhaging occurred in 4% (8 of 200) of the patients. The Cleveland Clinic's most recent series of 800 cases illustrates the decrease in the incidence of complications

associated with the procedure. Specifically, incidence of hemorrhage requiring surgical or radiologic intervention decreased to 2.1% of patients. The authors also noted a direct correlation between an increase in size of the lesion and the incidence of hemorrhage [24].

Management

Venous hemorrhage

Venous bleeding as the result of PCNL is usually self-limiting. During the procedure, the Amplatz sheath may tamponade the bleeding. However, if visualization cannot be maintained by placement of a sheath and/or removal of the clots, then the next step should be placement of a large 24F re-entry nephrostomy tube, which is then clamped to allow for clotting and hemostasis.

If conservative management fails, then a Kaye tamponade balloon catheter (Cook Medical Inc, Bloomington, IN, USA) can be used [25, 26]. The Kaye catheter tamponades the nephrostomy tract, but also effectively drains the renal pelvis and maintains ureteral access [25, 26]. The Kaye balloon must be positioned so that it occludes the bleeding vessel(s). If a Kaye balloon is not available, then a Council-tip catheter can be inflated in the renal parenchyma to tamponade the venous bleeding [27].

Perinephric hematoma

Post PCNL, a perinephric hematoma is a common finding. Extracorporeal shock-wave lithotripsy (ESWL) prior to PCNL increases the risk for developing a perinephric hematoma, as well as after LPN. A perinephric hematoma is usually clinically insignificant; however, if the hematocrit continues to decrease postoperatively, then a significant perinephric hematoma should be suspected despite clear urine output from the nephrostomy tube or voided specimens. The diagnosis can be confirmed with a triphasic abdominal CT scan to distinguish it from urinary leak. Initial management should consist of transfusion of crystalloids and blood products. If conservative measures fail, then renal angiography and superselective embolization should be performed in an attempt to identify and embolize the bleeding arterial branches. Once the hematoma liquefies and if the patient is symptomatic, then a percutaneous drain could be placed. In some cases, a return to the operating room for open exploration could be warranted.

Arterial hemorrhage

Postoperatively, patients can present with acute or delayed hemorrhage. This is usually exacerbated by strenuous activity and/or restarting anticoagulation therapy. Two large series have reported that patients who have undergone a LPN present with delayed hemorrhage at a median of 12 [28] and a mean of 17 [29] days post procedure.

Postoperative hemorrhage may present acutely with gross hematuria, dizziness, and/or hypovolemic shock. After stabilization with crystalloids and blood products, patients should undergo renal angiography and superselective embolization. The first reported use of renal artery embolization to control hemorrhage was in 1973 by Bookstein *et al*. [30]. The rate of postoperative hemorrhage requiring angioembolization has been consistent at 0.8–1.3% throughout the last 20 years in patients undergoing PCNL [31, 32]. With respect to LPN, Singh and Gill reported a 1.7% incidence of patients requiring embolization for treatment of postoperative hemorrhage [28]. The most common findings on angiography are arteriovenous fistulas, pseudoaneurysms, and lacerated renal segmental arteries (vessel cut-off) (Figure 30.2) [31, 32] (Further details of arterial embolization are described in Chapter 119.).

A recent publication from the University of California San Francisco group described its experience treating renal trauma [33]. A clinical success rate of 85% was achieved with selective embolization in patients with grade I–IV renal trauma after conservative management had failed. In a multiinstitutional review of 10 sites, the success rate reached 90% (151 of 167) utilizing renal angioembolization as a therapeutic intervention in the treatment of renal trauma [33]. Grade V renal trauma still requires surgical exploration.

In a series of 4695 patients who underwent PCNL for various indications, 1.2% postoperatively required angioembolization [32]. Also, similar data were obtained for patients undergoing LPN; 1.89% (7 of 370) [29]. Currently, there are no strict indications for renal angiography post PCNL. At our institution, when postoperative patients present with gross hematuria with clots, hypotension, or decreasing hematocrit that does not respond to conservative management, they are referred for angiography and possible embolization.

Conclusions

Postoperative renal hemorrhage is a well-known complication of minimally invasive renal procedures. It is important that patients are advised of this risk and that urologists be cognizant of management protocols. The majority of hemorrhagic complications can be managed with conservative measures and selective renal angioembolization. It is very rare to perform exploratory laparotomy and nephrectomy for failed renal angiographic management of postoperative hemorrhagic complications.

CHAPTER 31

Diagnosis and Management of Thoracic Complications of Percutaneous Renal Surgery

Jennifer Yates[1] & Ravi Munver[1,2]

[1]Hackensack University Medical Center, Hackensack, NJ, USA

[2]University of Medicine and Dentistry of New Jersey, Newark, NJ, USA

Introduction

Percutaneous renal surgery has evolved significantly since the first percutaneous nephrolithotomy (PCNL) was reported by Goodwin *et al*. in 1955 [1]. While the management of large and complex stone disease remains the most common application for percutaneous renal surgery, the approach is also well-suited for the minimally invasive treatment of ureteropelvic junction obstruction, select upper tract urothelial carcinomas, and ablative therapy for small renal masses. As a minimally invasive treatment modality, percutaneous renal surgery is associated with a unique set of complications, including bleeding from or damage to the kidney, and injury to nearby structures. The type of percutaneous renal access determines in part the risk of surrounding tissue injury. Solid organs, such as the spleen and liver, can be injured with an upper pole access, which usually manifests with significant bleeding. A retrorenal portion of the colon can predispose to a colonic injury. Finally, injury to the pleura and lung can occur, usually in the setting of upper pole or supracostal renal access. Thoracic complications, which include pneumothorax, hydrothorax, hemothorax, and nephropleural fistula, will be the focus of this chapter.

Injury to the lung and pleura can occur with access through any renal calyx, however the incidence increases significantly with upper pole and supracostal access. Renal anatomy determines whether access to a particular calyx will require a supracostal or subcostal approach. Many upper pole renal access sites are supracostal, although a small number may be subcostal, particularly in kidneys situated more caudally. Similarly, access into a mid or lower pole calyx may be supracostal in more cephalad kidneys. In some cases, subcostal access into a mid or lower calyx that is situated relatively high in the retroperitoneum can traverse the diaphragm and pleura. As such, each individual patient's anatomy must be taken into consideration. The indications for supracostal or upper pole renal access are discussed in Chapter 16.

Thoracic complications

Thoracic complications include pneumothorax, hydrothorax, hemothorax, and nephropleural fistula, with the possibility of more than one of these conditions coexisting. The incidence of these complications ranges from 0% to 18%, varying in part due to the type of renal access obtained. Table 31.1 lists the pleural complication rates of PCNL by series, including a description of reported complications. Pneumothorax can occur via the introduction of air into the pleural space while obtaining access or during the procedure, and to a lesser degree during nephrostomy tube removal. Alternatively, an injury to the lung can also result in a pneumothorax, although this complication is less commonly reported. In the case of injury to the lung parenchyma, a tension pneumothorax can develop.

Hydrothorax can occur when irrigation fluid or urine enters the pleural space along the nephrostomy tract or from diaphragmatic irritation with a reactive effusion. Picus *et al*. proposed two theories to explain the evolu-

tion of the pleural effusion after PCNL [2]. First, inadequate tamponade of the percutaneous nephrostomy tract combined with inadequate drainage of the kidney after the procedure can result in a fluid collection. Second, failure to seal the tract with a working sheath during the procedure can allow irrigant and urine to freely efflux into the pleural space.

Hemothorax is usually the result of an injury to the intercostal artery, diaphragm, renal parenchyma, or renal vasculature, with subsequent bleeding into the pleural space. Similar to the pathophysiology of hydrothorax, bleeding from the kidney can also track along the nephrostomy tube tract into the pleural space. Romero *et al*. reported two cases of hemothorax after percutaneous

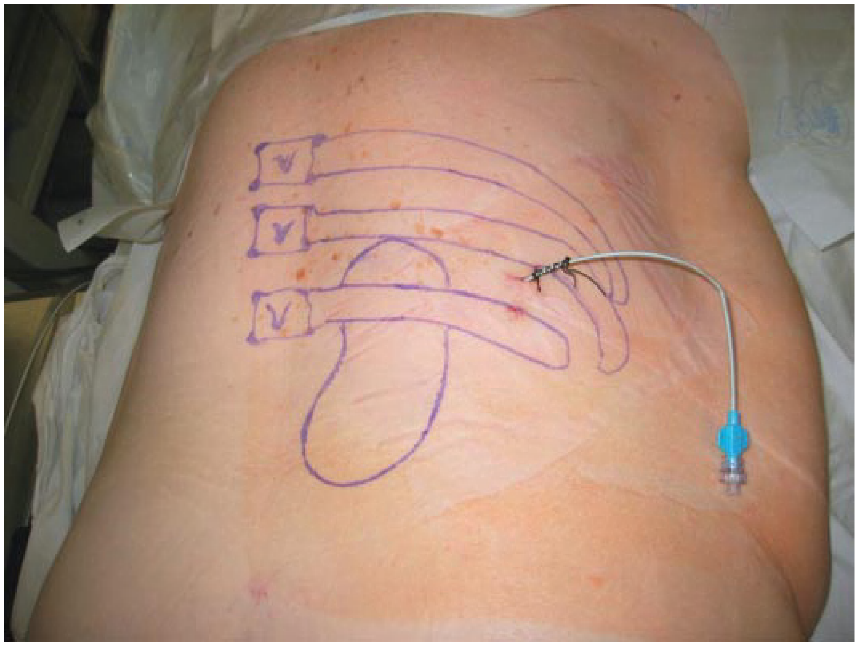

Figure 31.1 Upper pole renal access placed in preparation for percutaneous nephrolithotomy. The nephrostomy tract is placed in a supracostal position above the 12th rib, lateral to the midscapular line.

renal cryoablation of a renal mass [15]. The authors suggest the cause of these complications may have been injury to the phrenic or subcostal vessels, or a local irritative process from direct contact between a retroperitoneal hematoma and the posterior diaphragm.

Nephropleural fistula, the persistent drainage of urine from the renal collecting system into the pleural space, is similar to hydrothorax. While hydrothorax usually presents early in the postoperative course due to fluid collection during or shortly after the procedure, a nephropleural fistula often occurs later after nephrostomy tube removal. Development of a nephropleural fistula can be associated with distal collecting system obstruction.

Anatomy

An understanding of the diaphragmatic, pleural, and lung anatomy is critical to minimize thoracic complications. The diaphragm is attached to the inferior border of the 12th rib, the transverse process of the first lumbar vertebrae, and the anterior surfaces of the upper lumbar vertebral bodies. As a result, percutaneous access between the 11th and 12th ribs typically involves traversing the diaphragm.

The lung is enveloped by two layers of pleura. The visceral pleura is closely associated with the lung, and the parietal pleura covers the ribs, diaphragm, and mediastinal structures. The pleural space lies between the visceral and parietal pleura, with only a small amount of fluid occupying this space. The lower limit of the parietal pleura courses over the 12th rib obliquely, such that the lateral half of the rib is not covered by pleura. Percutaneous renal access over the lateral half of the 12th rib is preferable to avoid pleural violation. In the midscapular line, the visceral pleura extends to the 10th rib. Both the visceral and parietal pleura rise with expiration, and therefore percutaneous access lateral to the midscapular line below the 10th rib during expiration should serve to avoid the visceral pleura. Figure 31.1 demonstrates upper pole, supracostal access above the 12th rib. The nephrostomy tube was placed lateral to the midscapular line.

Hopper and Yakes evaluated the risk of lung and solid organ injury during posterior intercostal renal access [16]. Patients were imaged with computed tomography (CT) during full inspiration and expiration, and a line was drawn on the CT image from the upper pole of the kidney to the upper margin of the 11th and 12th ribs. The authors found that the phase of respiration had little effect on the relationship between the upper pole calyx and the 11th and 12th ribs in the prone and supine positions. When access above the 12th rib was considered, 29% of punctures on the right and 14% on the left would have traversed the lung if performed during full expiration. These percentages increased to 86% on the right and 79% on the left if the puncture was performed during full inspiration.

Risk factors for thoracic complications

Supracostal percutaneous renal access can provide an optimal approach for complex stones, but is associated with a higher risk of thoracic complications as compared

to a subcostal access. In a review of 464 patients who underwent upper pole PCNL, the incidence of chest complications in the supracostal group was 15.3%, with 5.3% requiring drainage of the pleural space. In contrast, the incidence was 1.4% in the subcostal group, with only 0.3% requiring drainage [17]. Similarly, Radecka *et al*. found a substantially higher rate of thoracic complications with the supracostal approach [8]. The authors also noted that pain associated with respiration was significantly higher in the supracostal group (32%) compared to the subcostal group (5%), which may potentially increase the risk of postoperative respiratory complications. Another study comparing 103 patients undergoing PCNL via a supracostal approach, and 39 patients via a subcostal approach, found a lower overall complication rate with the supracostal approach [18]. The incidence of chest complications was similar, with one case of hemothorax (1%) in the supracostal group and one case of pneumothorax (2.6%) in the subcostal group. Obesity was a major contributing factor in the overall complication rate, with the supracostal hemothorax occurring in an obese patient. Yadav *et al*. reported a 10-fold higher incidence of chest complications in patients who received a supracostal approach as compared to a subcostal approach [13]. While the supracostal approach may be associated with a higher thoracic complication rate, it is often preferred as a successful procedure is more likely. The authors reported that the majority of cases requiring supracostal access involved complicated stones, such as staghorn calculi or impacted upper ureteral stones. While the thoracic complication rate is reportedly lower with a subcostal approach, patients with complex stones are likely to benefit from improved stone clearance associated with a supracostal approach.

The incidence of thoracic complications also increases when a more cephalad intercostal space is used for access. Munver *et al*. reviewed 240 patients who underwent percutaneous renal surgery, including 98 patients with supracostal access [6]. Of these patients, access was obtained in the 10th intercostal space in 26 patients and in the 11th intercostal space in 72 patients. Thoracic complications occurred after eight procedures, of which seven were via a supracostal access. Of these seven thoracic complications, six occurred in the 10th intercostal space group and one in the 11th intercostal space group. The authors concluded that access via the 10th intercostal space is associated with a 16-fold higher thoracic complication rate when compared to the 11th intercostal space, and a 46-fold higher rate when compared to subcostal access. In another series, Shaban *et al*. reported two thoracic complications in a series of 30 patients undergoing percutaneous renal surgery via a supracostal approach [19]. Both of these complications occurred in patients with 10th intercostal space access. Based on these findings, the authors recommended that access above the 11th rib should be performed only by those with significant experience and only when the benefits of this access outweigh the risks.

Intraoperative technical factors may also increase the risk of thoracic complications. Young *et al*. reported a series of 24 patients who underwent PCNL via a supracostal access [20]. One patient developed a large hydrothorax requiring drainage of 1500 mL of fluid. A working sheath had not been used during this procedure, and the authors suggested that use of a working sheath may have prevented this complication.

Renal access may be obtained either by a radiologist or urologist, depending on the urologist's training and an institution's protocol. Watterson *et al*. reviewed access-related complications during a series of percutaneous nephrolithotomies and found no difference in the complication rate when the access was performed by a radiologist or urologist [21].

In summary, a more cephalad access site increases the risk for thoracic complications. Renal access above the 11th rib is associated with a marked increase in complication rates. Technical factors may also contribute to the development of complications, such as avoiding use of a working sheath. The sheath should be advanced into the renal collecting system to decrease efflux of irrigation into the retroperitoneum and pleural space. While it is difficult to accurately measure the volume of irrigant infused, an obvious discrepancy between the inflow and outflow of irrigant should alert the surgeon to a potential problem. In this case, fluoroscopy can be used to inspect the costophrenic angle to evaluate for hydrothorax.

Diagnosis

The diagnosis of pleural injury is ideally made intraoperatively, at which time it may be treated expeditiously and with minimal patient discomfort. Alterations in ventilatory parameters may indicate pleural violation and should prompt fluoroscopic evaluation to search for a pneumothorax or hydrothorax. Even in the absence of ventilatory changes, fluoroscopic evaluation of the lung and costophrenic angle should be performed at the end of the procedure. This complication can also be diagnosed in the postoperative period either based on routine chest imaging or the development of signs and symptoms.

Another intraoperative indication of a thoracic complication is significant bleeding through the nephrostomy tract. While this may occur from a renal vascular injury, the surgeon should be suspicious of an intercostal artery injury in cases using a supracostal approach. Figure 31.2A shows bleeding from a supracostal renal access sheath during PCNL in a patient who developed a hemothorax from intercostal artery injury. Figure 31.2B shows the poor visualization during nephroscopy due to extensive bleeding.

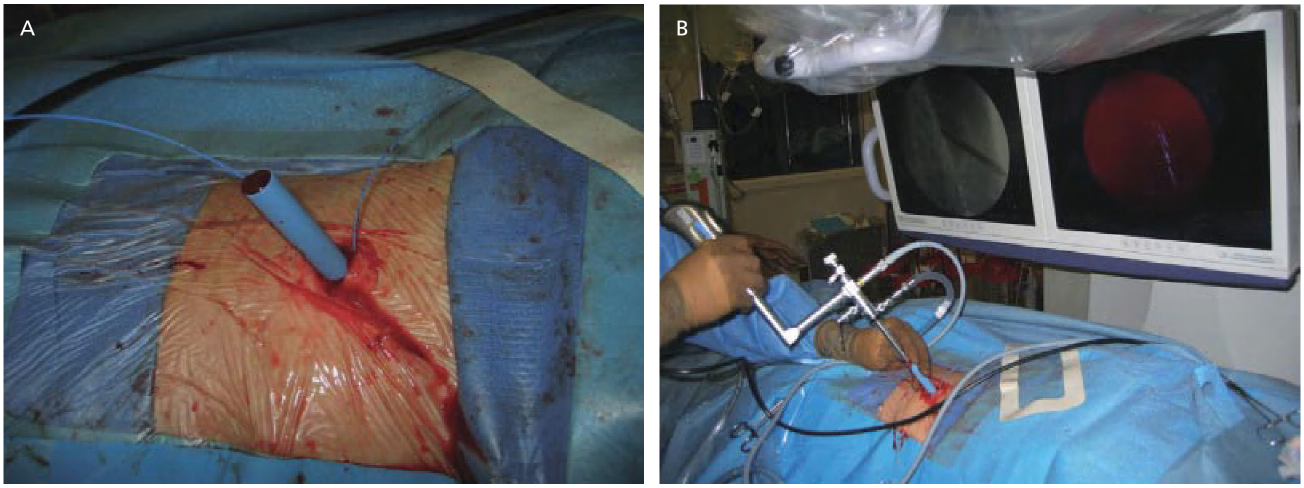

Figure 31.2 (A) Hemorrhage following injury to an intercostal artery as elicited by bloody output from an access sheath placed via a supracostal access tract. (B) Compromised nephroscopy due to excessive bleeding. Left screen shows cephalad angulation of nephroscope; right screen shows the obscured view due to bleeding.

Figure 31.3 Chest CT scan demonstrating right hydrothorax after supracostal percutaneous nephrolithotomy. Note fluid layering in the right hemithorax (photograph courtesy of Dr Glenn Preminger).

Some surgeons advocate chest X-ray (CXR) after all supracostal percutaneous renal procedures. On a posterioanterior CXR, a meniscus is visible when 175–200 mL of fluid is present in the costophrenic sulcus [22, 23] and the hemidiaphragm is obscured with 500 mL [23]. Chest CT can also be used to detect a pleural fluid collection or pneumothorax, although it may also demonstrate clinically insignificant pathology due to its high sensitivity [24]. Figure 31.3 shows a right pleural fluid collection after supracostal PCNL. Ogan *et al*. compared the sensitivity of CXR, chest CT, and intraoperative chest fluoroscopy in detecting hydropneumothorax [24]. Fluoroscopy was performed at the completion of the PCNL procedure to evaluate for pleural fluid, and tube thoracostomy was performed if indicated. All patients underwent CXR in the recovery room. CT was performed in the postoperative period to evaluate for residual stone burden, with the CT imaging including the lung bases as per the radiology protocol. Of the 104 percutaneous renal accesses performed in the study, 58% were supracostal. Fluoroscopy detected pleural fluid in one patient (1%), CXR detected hydrothorax in 8%, and chest CT detected hydrothorax in 38%. With CT diagnosis serving as the reference standard, intraoperative fluoroscopy had a false-negative rate of 59.6% and a 0% false-positive rate. Similarly, postoperative CXR was associated with a 48.4% false-negative rate and 2.6% false-positive rate. An intervention for hydropneumothorax was necessary in seven patients, all of whom had undergone a supracostal access. Interventions outside of the operating suite were performed for a large hydropneumothorax or the presence of symptoms; however, no interventions were performed solely on the results of the postoperative CXR. The authors concluded that routine CXR in the recovery room is unnecessary, and the development of symptoms or the findings of a large effusion on CT may warrant intervention. Intraoperative fluoroscopy and postoperative CXR, when indicated, are usually sufficient to diagnose a thoracic complication. Renal scintigraphy has been described to aid in the diagnosis of a case of urinothorax after PCNL, though the clinical application of this modality is limited [25].

In the postoperative period, the diagnosis of a thoracic complication is often based on the patient's symptoms. Complaints may include shortness of breath or chest pain, with objective findings including increasing oxygen requirement and decreased breath sounds over the affected lung field. In one series of 102 supracostal PCNL procedures, 10 patients were diagnosed with

thoracic complications. Four patients were diagnosed intraoperatively before extubation, three were diagnosed in the recovery room based on oxygen desaturations, and three developed shortness of breath and tachypnea several hours later after transfer to the surgical floor [5].

Nephropleural fistula is a unique complication, often presenting later in the postoperative course after nephrostomy tube removal. Lallas *et al*. described a series of 375 patients undergoing percutaneous renal surgery, including supracostal access in 26% of the procedures [26]. Four patients were diagnosed with nephropleural fistula after nephrostomy removal, two of which presented immediately. The diagnosis was made on the basis of a retrograde pyelogram. In cases of persistent drainage from a chest tube placed for hydrothorax, a nephropleural fistula should be considered. Patients with signs or symptoms of pulmonary complications, either early in the postoperative period or after nephrostomy removal, should initially be evaluated with physical exam and CXR. Based on these findings, a retrograde pyelogram may be necessary to document a fistulous connection between the collecting system and pleural space after supracostal PCNL (Figure 31.4). Persistent drainage suggests the possibility of distal ureteral obstruction, which can also be assessed with a retrograde ureteropyelogram.

Prevention

Prevention of thoracic complications begins with an assessment of the anatomic relationship between the kidney and pleural space, and a determination of the appropriate access site. As described earlier, the parietal pleura courses over the 12th rib in an oblique fashion, such that the lateral half of the rib is not covered by pleura. At the beginning of the procedure, fluoroscopic evaluation can assist in identifying the inferior pleural margin. Biplanar fluoroscopy may provide superior visualization of the anatomic relationship between the kidney and pleural space, and decrease the risk of complications [9]. Supracostal access should be performed lateral to the midscapular line to minimize injury to the pleura. The needle should be advanced along the upper margin of the rib during shallow breathing or during the expiratory phase. Needle passage along the inferior margin of the rib risks injury to the intercostal neurovascular bundle, which can result in significant bleeding. Some authors have recommended calyceal entry during inspiration to displace the kidney caudally [27].

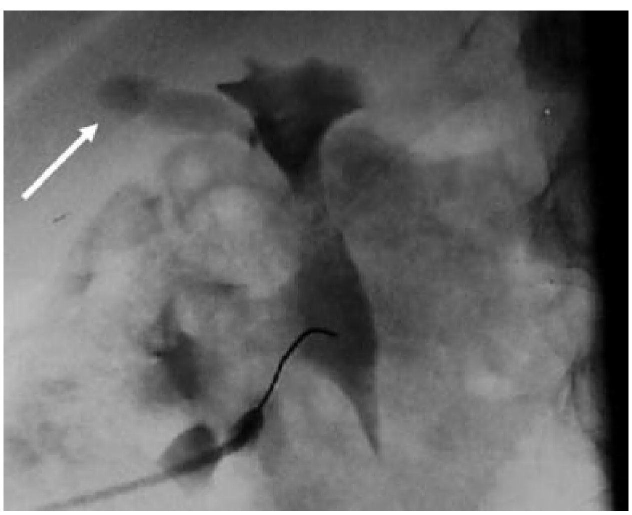

Figure 31.4 Nephrostogram showing a fistulous communication between the collecting system and the pleura. Arrow points to the nephropleural fistula (photograph courtesy of Dr Glenn Preminger).

Pedro *et al*. describe a technique of renal displacement to allow the renal access to be obtained more caudally than would otherwise be possible [28]. If the targeted calyx is above the 11th rib, the authors place an extra access site into a mid–posterior calyx to help displace the kidney caudally. This access site can also be used for postoperative drainage. A similar recommendation, using either saline or carbon dioxide, was described by Romero *et al*. to minimize the risk of hemothorax during percutaneous renal mass cryoablation [15]. The injection of saline or carbon dioxide displaced the kidney caudally away from the diaphragm. Displacing the kidney in this manner also minimizes diaphragmatic irritation from extravasated blood products.

Once access has been obtained and the tract dilated, an access sheath should be utilized to minimize extravasation of irrigant into the retroperitoneum and pleural space. In the event that the parietal pleura is traversed by the needle, the use of an access sheath can often prevent this from evolving into a thoracic complication. The amount of irrigant used during the procedure should be monitored, although a precise measurement is difficult. If the inflow of irrigant is significantly more than the measured outflow, the possibility of extravasation into the pleural space should be considered, and the chest fluoroscopically evaluated.

Postoperative renal drainage after percutaneous nephrolithotomy is based on the site of access, amount of stone burden, degree of collecting system trauma, plan for a second-look procedure, and surgeon preference. Blood clots or stone fragments that may pass into the ureter can cause ureteral obstruction, potentially resulting in a nephropleural fistula. In many patients, a nephrostomy tube is left in place for a minimum of 24 h following the procedure. If a nephrostomy tube is left at the end of the procedure, the appropriate position within the collecting system is of importance. An antegrade nephrostogram can help to ensure that the catheter is well-positioned. Shaban *et al*. described a case

of a nephropleural fistula 2 days after PCNL in a patient with dyspnea, chest pain, and fever [19]. An antegrade nephrostogram demonstrated one side-hole of the nephrostomy tube to be outside of the kidney, with extravasation of urine into the pleural space. The patient was managed with a thoracostomy tube and an internal ureteral stent.

Kim *et al*. described the use of a lower pole nephrostomy tube for drainage after percutaneous renal surgery through an upper pole access site [11]. The 62 patients included in the study underwent upper pole renal access, with the upper pole access site left tubeless at the end of the procedure. Patients were included only if they had minimal or no stone fragments at the end of the procedure. A subcostal nondilated access site was utilized for the nephrostomy tube, providing drainage and secondary access if needed. The authors suggest that this technique minimizes patient morbidity.

Thoracic complications following tubeless PCNL will be addressed at the end of the chapter.

Management

One of the most important tenets of the management of thoracic complications is early diagnosis when possible. Patients with supracostal access should be regarded as high risk for thoracic complications. At the conclusion of each percutaneous renal surgery procedure, the lung field and costophrenic sulcus should be closely evaluated with fluoroscopy. Pneumothorax, hydrothorax, and hemothorax may be noted at this time, and a thoracostomy tube may be placed while the patient remains anesthetized.

A relatively small pleural effusion or pneumothorax noted on intraoperative fluoroscopy, in the absence of any changes in ventilatory parameters, may be managed conservatively or with simple needle aspiration. When a large pleural effusion or pneumothorax is noted intraoperatively, a thoracostomy tube should be placed. Ogan and Pearle describe the intraoperative placement of a chest tube using fluoroscopic guidance [29]. A Chiba needle is inserted along the posterior axillary line under fluoroscopic guidance until it is seen in the fluid-filled pleural space. A nitinol wire is then passed through the needle, and a wire guide exchange set can be used to replace the nitinol wire with a larger caliber guidewire. A 10F nephrostomy tube is passed over the guidewire, positioned at the base of the pleural cavity, and the tube is connected to a pleur-evac set-up. If bloody fluid is encountered, a larger tube should be used. The authors state that the tube can usually be removed within 24–48 h when drainage has resolved.

In the postoperative period, the management of hydrothorax depends on the size of the effusion and the degree to which the patient is affected. Minimal blunting of the costophrenic angle can usually be managed conservatively [7]. Large or symptomatic effusions should be treated with drainage of the pleural space. Needle aspiration can relieve a smaller effusion, but tube thoracostomy should be used for larger effusions. The thoracostomy output and CXR are monitored, and with resolution of drainage and the effusion, the tube can be removed. Typically, the average duration of chest drainage is 3–4 days [7]. If a second-look PCNL is planned, the thoracostomy tube should be left in place until after this procedure is completed [29].

As described previously, nephropleural fistula can occur much later in the postoperative course. When suspected, a retrograde pyelogram can be diagnostic. If a fistulous connection is seen, an indwelling internal ureteral stent can be placed at that time. In most cases, decompression of the collecting system with a stent and the pleural space with a thoracostomy is indicated [26]. If a stent had been placed at the time of the percutaneous renal surgery, urine reflux from the bladder may be a contributing factor for persistent drainage. The bladder should remain decompressed with a urethral catheter until the thoracostomy tube output decreases.

A diagnostic and treatment algorithm can be proposed based upon the preceding discussion. Intraoperatively, the ipsilateral lung field and costophrenic angle should be assessed fluoroscopically, especially in patients undergoing supracostal or upper pole renal access. If a large effusion is noted, the effusion can be drained, with a thoracostomy tube left in place if a significant amount of fluid is obtained. If the costophrenic angle is partially obscured without a large pleural effusion, the patient can be clinically monitored or receive a CXR in the recovery room [30]. In the postoperative period, signs or symptoms that raise suspicion for a thoracic complication should prompt a CXR. If a clinically significant pleural effusion or large pneumothorax is encountered, a tube thoracostomy should be placed at that time. Alternatively, if the effusion is small and is not consistent with a hemothorax, then needle drainage alone is sufficient. In the event that the effusion is bloody, a larger tube thoracostomy would provide sufficient drainage. In the patient who develops signs or symptoms of a thoracic complication later in the postoperative course, especially in the setting of recent nephrostomy removal, a nephropleural fistula should be considered. The first diagnostic test is a CXR, and if a pleural effusion is noted, a retrograde pyelogram should be performed. If the retrograde pyelogram demonstrates a fistulous connection between the renal collecting system and the pleural space, an indwelling ureteral stent is placed, usually in conjunction with a thoracostomy tube. A pneumothorax immediately after nephrostomy removal is often small, resulting from the introduction of air into the pleural space during tube

removal. If symptoms are minimal and the pneumothorax is small, no other treatment is necessary. Alternatively, tube thoracostomy may be considered.

A unique set of complications can develop in the setting of an undrained or poorly drained hemothorax, including empyema and fibrothorax. These complications are well-described in the general surgery literature as sequelae of traumatic hemothorax. A general or thoracic surgery consult should be obtained early in the course of a complex hemothorax to improve outcomes. Early evacuation of a hemothorax is critical to decrease the risk of these complications as well as minimize the invasiveness of the management protocol. The goal of early drainage is to prevent formation of loculations, which occur approximately 7 days after the initial injury [31]. If a retained hemothorax is noted after thoracotomy tube placement, a second thoracotomy tube may be placed. Some authors suggest that a trial of intrapleural streptokinase may be effective early in the course [31]. If a second thoracotomy tube fails to fully drain the hemothorax, thorascopic evacuation can be performed [32, 33]. Thorascopic evaluation is best performed within the first 5 days after injury to improve the success rate and minimize additional complications [32]. A poorly drained hemothorax can develop into an empyema, increasing the complexity of treatment. As the empyema evolves, a visceral "peel" develops, leading to parenchymal trapping [31]. Finally, fibrothorax can occur, which is characterized by diffuse pleural thickening and leads to respiratory compromise. Although rare, this complication is difficult to manage, often requiring surgical intervention with debridement [34].

Pediatric patients

Pediatric patients represent a unique population in the treatment of stone disease. More centers are gaining experience with pediatric PCNL and have accrued significant experience with complex stone disease. The indications for upper pole and supracostal renal access are similar in the adult and pediatric populations. El-Nahas *et al*. described 50 pediatric patients who underwent 60 PCNL procedures [27]. Supracostal access was obtained in 20 of the procedures and subcostal access in the remaining 40 procedures. There were no thoracic complications in any of the patients, and the overall complication rate between the two groups was similar. Stone-free rates were also comparable in each group.

Techniques to minimize the risk of thoracic complications in pediatric patients are similar to those in the adult population. These include avoiding the 10th intercostal space approach when possible, accessing the kidney over the lateral portion of the rib, and identifying the inferior pleural margin using fluoroscopy. While El-Nahas *et al*. report excellent results with pediatric supracostal PCNL, the report represents the experience of a high-volume pediatric stone center. Institutions with less pediatric stone experience may note higher thoracic complication rates, and this approach should be used with caution.

Tubeless percutaneous nephrolithotomy

Tubeless PCNL is gaining popularity as it is associated with decreased postoperative pain, analgesia requirement, and a shorter hospital stay. However, some surgeons are reluctant to consider tubeless PCNL when a supracostal access site is used. Shah *et al*. described 454 tubeless PCNL procedures using 535 renal tracts, of which 358 were supracostal [35]. The authors found that tubeless PCNL was not associated with more chest complications compared to standard PCNL in which a nephrostomy tube is left at the end of the procedure. Jou *et al*. caution surgeons to monitor for delayed complications, reporting a delayed pneumothorax 1 day after PCNL performed through the 11th intercostal space [36].

In summary, tubeless percutaneous nephrolithotomy is likely safe in appropriately selected patients, and with close attention paid to fluoroscopic evaluation of the lung field and costophrenic angle at the completion of the procedure.

Conclusions

Percutaneous renal surgery has gained in popularity for a variety of applications within the past decade. Surgeons have become more comfortable with the percutaneous treatment of complex stone disease. Many of these complex cases are best approached utilizing a supracostal access to increase success rates. While the supracostal access often offers a higher stone-free rate in these patients, it is also associated with a higher rate of thoracic complications. An appreciation for renal and pleural anatomy can help decrease the risk of these complications. Close radiographic surveillance of the lung field and costophrenic angle during the procedure can identify complications early, allowing prompt management that is more tolerable for the patient. In the postoperative period, the surgeon must be attuned to the signs and symptoms of thoracic complications, and be prepared to manage such complications in the event that they arise.

CHAPTER 32

Bowel and Other Organ Injury during Percutaneous Renal Surgery

Saeed Al-Qahtani & Olivier Traxer

Tenon University Hospital, Pierre and Marie Curie University, Paris, France

Colon injury

Colonic perforation is a rare complication during percutaneous renal surgery, reported in about 1% of cases [1–6]. This low incidence is likely the result of the colon rarely being retrorenal (reported in approximately 0.6% of the general population [7, 8]). A retrorenal colon is most frequently noted on the left side and is most likely to be situated near the inferior pole of the kidney (Figure 32.1) [9]. Hopper *et al.*, in a study of 500 computed tomography (CT) scans of the abdomen, reported that the overall frequency of retrorenal colon in the supine patient was 1.9% [10, 11]. When 90 patients were studied in the prone position, a retrorenal colon was found in 10%. A puncture site laterally may increase the risk of colon injury. The position of the colon is usually anterior or anterolateral to the lateral renal border. Therefore, risk of colon injury usually exists only with a very lateral (lateral to the posterior axillary line) puncture.

Risk factors

Displacement of the colon posterior to the kidney increases the risk of colon perforation, and is seen in elderly patients with chronic constipation or patients with other causes of colonic distention, patients with previous major abdominal surgery (jejunoileal bypass, partial jejunoileal bypass), neurologic impairment, and institutional bowel resulting in an enlarged colon. Others at greater risk include thin female patients with little retroperitoneal fat, and patients with mobile kidneys, anterior calyceal puncture, previous extensive renal surgery [11, 12], horseshoe kidney and other forms of renal fusion or ectopia [13, 14], and kyphoscoliosis (Figure 32.2) [7, 15–18].

Ultrasound-guided renal percutaneous access can be performed in patients at increased risk of having a retrorenal colon [19]. A preoperative CT scan with the patient in the prone position is strongly recommended if there is any concern for colonic injury. For some, CT-guided access should be considered if the window of entry into the collecting system may be quite small [20].

Diagnosis

Prompt, early recognition of a colonic perforation is essential to limit serious infectious consequences. Colonic perforation should be suspected if the patient has intraoperative or immediate postoperative diarrhea or hematochezia, signs of peritonitis, or passage of gas or feces through the nephrostomy tract [21]. Otherwise, postoperative nephrostography before nephrostomy removal can reveal the presence of colonic contrast. Sepsis has been reported to occur in 0.6–1.5% of patients who undergo percutaneous stone removal [2, 22–24]. Antibiotic therapy, fluid resuscitation, and even the administration of pressors may be necessary to treat these patients. If the patient's condition does not improve with these measures, CT imaging is recommended to assess for unsuspected abdominal, retroperitoneal complications that contribute to sepsis, such as colonic perforation.

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Treatment

The majority of patients with colonic injuries can be treated without open surgical intervention if the penetration is retroperitoneal and the patient does not have peritonitis or sepsis [25]. An indwelling double-J stent is inserted, the nephrostomy tube withdrawn under fluoroscopic guidance into the colon (Figure 32.3), and a Foley catheter left in place in the bladder to maintain a low urinary pressure system. The patient should be given broad-spectrum antibiotics or triple antibiotic coverage and be on a low-residue diet. This allows the renal collecting system to heal and the medial colonic wall to close. After 5–7 days, if the colostogram or a retrograde pyelogram shows neither extravasation nor colonic communication with the collecting system, the Foley catheter is removed and the colostomy tube withdrawn but still kept as a drain outside the colon. After 2–3 days (7–10 in total), when the lateral colonic wall is expected to have closed, and if there is no evidence of a persistent nephrocolic fistula, the tube is then completely removed [3, 5–7].

In case of intraperitoneal colonic perforation, peritonitis, sepsis, or failed conservative management, open surgical exploration should be performed, and a colostomy is usually necessary.

Some authors have reported on the nonoperative management of a nephrocolic fistula that resulted from percutaneous nephrostolithotomy with adequate urinary and colon drainage, elemental diet, and antibiotic coverage. In 1983, Vallancien *et al*. reported two cases with perforation of the left colon among a series of 250 percutaneous nephrolithotomies (PCNLs) [6]. These two cases were both men with mobile kidneys.

Figure 32.1 Nephrostomy tube transverses the left colon (retrorenal colon). Colonic injury during supine percutaneous nephrolithotomy (courtesy of Pr Bertrand Dore).

Figure 32.3 Nephrostomy tube is seen (arrow) in the right colon after colonic injury during a right percutaneous procedure.

Figure 32.2 Patient with kyphoscoliosis and body deformities has high risk of colonic injury during nephrolithotomy.

The clinical signs were rectal hemorrhage with shock in one case and passage of gas through the nephrostomy tract in the other. The perforation was not suspected during PCNL, and both patients were treated surgically. The authors recommended open surgical repair when the perforation is intraperitoneal or there is a risk of complications, and simple surveillance when the perforation is extraperitoneal and there is no risk of complications.

Gerspach *et al*. reported on five patients with colonic injuries during percutaneous renal surgery (three on the left, two on the right) [25]. All had undergone PCNL, and all injuries were extraperitoneal. Three patients were considered lean, and the other two were of average body habitus. Recognition of colon injury occurred postoperatively in four patients and intraoperatively in one patient. Presenting signs and symptoms included fever, fecaluria, abdominal pain, and leukocytosis. The authors concluded that retroperitoneal colon injuries can be successfully managed conservatively with early recognition and appropriate drainage of the urinary and intestinal tracts. They also recommended, for high-risk patients, a more superior and medial puncture. More recently, El-Nahas *et al*. retrospectively reviewed 5039 PCNLs (1985–2004) and reported 15 (0.3%) colonic perforations [14]. The authors evaluated operative details and postoperative course to determine the time and mode of diagnosis of colonic injury, and treatment strategies and outcome. All injuries were retroperitoneal. Of the 15 patients (11 men, four women), the left side was affected in 10 (66.6%). The right side was injured only in those with horseshoe kidneys or with recurrent disease. Colonic perforation complicated lower calyceal puncture in 12 procedures (80%) and complicated upper calyceal punctures in those with horseshoe kidneys or chronic colonic distention. Significant independent risk factors for colonic perforation during PCNL were advanced patient age and the presence of a horseshoe kidney. The diagnosis was established intraoperatively in five patients and postoperatively in 10, five of whom presented with enterocutaneous fistula. The diagnosis was confirmed with abdominal CT or opacification of the colon during antegrade or retrograde pyelography. Conservative treatment was successful in all but two patients in whom a colostomy was necessary. El-Nahas *et al*. confirmed the conclusion of Gerspach *et al*. that early diagnosis and proper treatment represent the key to minimizing patient morbidity and avoiding serious complications, as have other authors, who have also recommended open surgical management in patients with transperitoneal perforation, peritonitis, or sepsis [3–6, 13].

In 1998, Wolf reported the principles of management of bowel injury during percutaneous stone extraction [18]. These principles include inspection of the PCNL tract for colonic injury whenever the tract is inspected for bleeding; a high index of suspicion for colonic injury when unexplained signs or symptoms of inflammation or infection develop postoperatively; and adequate drainage of both the colon and urinary collecting system.

Small intestine injury

The second and third portions of the duodenum may be injured during percutaneous renal surgery because they are adjacent to the right kidney, but this represents a very rare complication of PCNL and is rarer than colonic perforation. This can occur when the renal pelvis is perforated during dilation, or during placement of the working sheath or stone removal. This complication can be avoided with careful fluoroscopic monitoring during access, tract dilation, working sheath placement, and proper endoscopic manipulations. In 1985, Culkin *et al*. reported one case of a nephroduodenal fistula complicating PCNL that was managed conservatively [26]. The patient was discharged from hospital 14 days postoperatively, free of stone and doing well. The duodenum, positioned anteromedially to the right kidney, can be injured during right-sided percutaneous procedures if a needle or an instrument is advanced too deeply. In addition, it can be perforated if the back, stiff part of a guidewire is erroneously used for dilation of the nephrostomy tract.

Injury should be suspected if intestinal mucosa or contents are visualized or if communication with the small bowel is demonstrated on a nephrostogram or on the formation of a nephroduodenal fistula, which is also seen when postoperative nephrostography is obtained. In the face of a large perforation or patient instability, open surgical repair is necessary. For patients with small injuries of the small bowel and no signs of peritonitis or sepsis; however, nonoperative management may be attempted. For this group, antibiotics are administered and bowel rest is achieved with nasogastric suction and parenteral hyperalimentation. The nephrostomy tube should be positioned correctly to assure adequate drainage. Nephrostography and upper gastrointestinal radiography are performed 10–15 days after injury to assess for closure of the fistula [18, 26, 27].

Injury to adjacent structures

Pleura and lung (see also Chapter 31)

Pleura and lung complications are rare and most occur when the supracostal approach is used. Chest complications are the main morbidity associated with supracostal puncture during PCNL(0–12.5%). The majority of hydrothoraces are asymptomatic, and intervention is

necessary in only a small percentage (4%) of patients [28]. Lojanapiwat *et al*. performed a comparison of the supracostal and infracostal approaches [29], reporting rates of pulmonary complications of 15.3% and 1.4%, respectively. When the supracostal approach is used, complications may be reduced by positioning an Amplatz sheath well into the collecting system and placing a well-draining nephrostomy tube to minimize the leakage of urine into the pleural. Chest fluoroscopy is recommended intraoperatively; however, routine chest X-ray is not mandatory if fluoroscopy is normal in the absence of respiratory signs [30]. A chest tube is necessary if there is a large pneumothorax or hydrothorax with or without signs of respiratory compromise. Renopleural fistula has been and is usually resolved with the placement of a thoracostomy tube; nevertheless, persistence of thoracic fluid should alert the urologist to perform intrarenal stenting. Lallas *et al*. reported rates of nephropleural fistula after supracostal PCNL of 2.3% (two of 87 cases) and 6.3% (two of 32 cases) during supra-12th rib and supra-11th rib access, respectively [31]. The incidence of nephropleural fistula increased to 3.3% when supracostal access was performed. Proper attention to the technique and intraoperative and postoperative monitoring can detect chest complications, and these can easily be managed with either aspiration or intercostal drainage without serious morbidity or death.

Liver and spleen

Due to the close anatomic relationship of the kidney and spleen on the left side, and the liver on the right side, iatrogenic injuries are associated with renal surgery and percutaneous access; however, hepatic and splenic injuries during PCNL are uncommon. The early diagnosis and treatment of splenic injuries can prevent associated morbidity and mortality, as missed splenic injuries are potentially fatal. A heightened suspicion for vascular injuries or splenic trauma in the perioperative period should be considered in patients undergoing PCNL with excessive blood loss, hemodynamic instability, or severe abdominal pain. A careful review of preoperative imaging can identify anatomic variants, such as splenomegaly or a retrorenal colon or spleen [32]. The factors that may predispose the spleen to injury during percutaneous renal procedures include splenomegaly, an intercostal approach, site of access (a more lateral placement poses a greater risk), and retrorenal spleen [32]. The nonoperative management of splenic injuries was associated with a high mortality rate. However, advances in imaging and new grading systems of splenic injuries have allowed select patients to be successfully managed conservatively, thus avoiding laparotomy and splenectomy [33]. Splenic artery angioembolization may allow the nonoperative management of splenic bleeding in select cases [34]. Repeat CT imaging can be performed to detect early signs of active bleeding; however, emergent splenectomy is warranted if conservative management fails or for patients with evidence of hemodynamic instability.

Liver injury during PCNL is very rare. Hopper and Yakes performed CT at both maximal inspiration and expiration with sagittal reconstructions in 43 randomly selected patients [35]. They found that the liver and spleen were not in contact with the supra-12th tract, but if the supracostal puncture was performed above the 11th rib during full expiration, the liver was punctured in 14% of cases. Hepatomegaly is another risk factor, even if the tract is made through the 11th intercostal space; therefore, such patients should be evaluated with a preoperative CT scan. Management of hepatic trauma is usually conservative, and surgical exploration is rarely needed (only in hemodynamically unstable patients). The nephrostomy tube should be left in place for almost a week to allow for tract formation. Sealing the tract with fibrin through the liver parenchyma during withdrawal of the nephrostomy tube has been reported [36]. Removing the nephrostomy tube and inserting a double-J stent at the same time is recommended to avoid a renobiliary fistula.

Conclusions

Bowel and adjacent organ injury may occur during percutaneous surgery. Patients need to be informed about this specific risk. It represents an unusual complication that is often diagnosed by postoperative nephrostography or patient clinical signs. The retroperitoneal colon is usually encountered anteriorly or anterolaterally to the lateral renal border. Therefore, the risk of colon injury is usually low. Colonic perforation may occur when the puncture site is placed lateral to the proposed posterior axillary line or in the rare event of a patient with a retrorenal colon. Typically, the injury is retroperitoneal; thus, signs and symptoms of peritonitis are infrequent. The majority of patients with colonic injuries can be treated without open surgical intervention with conservative measures, including adequate urinary and colon drainage, total parenteral nutrition (TPN), and antibiotic coverage.

Splenic injury can cause recalcitrant problems, including hemorrhage, and may eventually mandate splenectomy. A high index of suspicion is necessary for early diagnosis in view of the variability in clinical presentation. Splenic preservation should be attempted whenever possible to avoid the long-term risks created by splenectomy. Liver injury resulting from PCNL can be managed conservatively provided diagnostic, monitoring, and operating room facilities are available.

Proper patient selection and preparation, meticulous operative technique, and close postoperative care help to prevent the occurrence and decrease the magnitude of these complications. Prompt diagnosis of the complication and appropriate measures to rectify the problem will also limit its impact.

CHAPTER 29
Exit Strategy After Percutaneous Renal Surgery: Drainage and Hemostasis

Arun K. Srinivasan, Zeph Okeke & Arthur D. Smith
The Smith Institute for Urology, North Shore – Long Island Jewish Health System, Long Island, NY, USA

History and introduction

Fernstone and Johanson first described percutaneous nephrolithotomy (PCNL) in 1976 [1] for the management of renal pelvic calculi. Since then, this technique has become an established treatment modality and the primary option for management of patients with large stone burden in the renal pelvis [2], ureteropelvic junction obstruction (UPJO) [3], and upper tract transitional cell carcinoma (TCC). There has been constant innovation and experimentation with new techniques in all aspects of percutaneous renal surgery, including access into the kidney, tools for surgery, including optics and instrumentation, and exit strategy. In this chapter we will discuss the last of these.

It was routine practice to leave a wide-bore nephrostomy tube after percutaneous renal surgery (which includes PCNL, antegrade endopyelotomy, and urothelial cancer resection) to address the twin issues of hemostasis and drainage. But these tubes were large, cumbersome, and a significant source of pain for patients, resulting in postoperative morbidity and hence the incentive for improvement. Urologists prompted improvements in the design of the nephrostomy tube with caliber reduction to improve outcomes [4]. Eventually they started questioning the very need for a nephrostomy tube itself. In 1997, Bellman *et al*. reported tubeless PCNL as an alternative to nephrostomy tubes as an exit strategy after PCNL [5]. Since then this technique has been reported to have multiple advantages, including decreased postoperative pain, shorter hospital stay, and decreased analgesic need [6].

The exit strategy after PCNL has been a topic of controversy in recent years. As mentioned, wide-bore nephrostomy tubes were placed routinely after percutaneous renal surgery both to drain the kidney, and tamponade the access tract and establish hemostasis (although there is no evidence to support this assumption). The nephrostomy tube also allows clearance of blood clot, provides an access for a nephrostogram to be performed in the postoperative period, and permits access into the collecting system for a re-entry procedure in a staged nephrolithotomy. Recently the routes to establish hemostasis and provide drainage have diverged into separate strategies.

Drainage of the kidney was addressed with placement of stents or even "totally tubeless" PCNL. Paralleling these changes in drainage aspect, new techniques were reported to establish hemostasis of the tract. These included using gelatin matrix hemostatic sealant [7], cauterization of tract and tissue sealants [8], and Surgicel to maintain hemostasis and aid closure of tract. We reported our experience with cryoablation of the nephrostomy tract with a single freeze–thaw cycle to establish hemostasis [9]. Together, these new techniques for drainage of the kidney and hemostasis may open new avenues of minimally invasive management, even for patients undergoing complicated PCNL.

We will discuss drainage and hemostasis in separate sections with detailed analysis of available evidence and possible recommendations.

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Drainage of the renal pelvis

It should be emphasized that the terminology of the newer drainage techniques needs to be standardized to achieve uniformity in reporting and avoid misconceptions. In this chapter, we define PCNL with a nephrostomy tube as "tubed PCNL," PCNL with ureteral stents only as "stented PCNL," and totally tubeless PCNL as "tubeless PCNL."

There are three main techniques for drainage of the collecting system after percutaneous renal surgery: nephrostomy tubes, ureteral stents, and totally tubeless surgery. It is important to mention that the options of ureteral stents and tubeless surgery have only been studied in low-risk PCNL and to some extent can be applied to antegrade endopyelotomy with necessary modifications. We do not have any evidence to use the modified drainage options in patients undergoing resection of TCC in the renal pelvis or ablation of calyceal diverticulum. Hence, the most important factors that should govern the technique for drainage of the kidney are indications for the procedure, operative course, procedural complexity, stone burden, and the clinical status of the patient. One universal solution is not applicable for all patients undergoing percutaneous renal surgery.

Nephrostomy tubes

"An ideal nephrostomy tube should be strong and biocompatible, well tolerated by the patient, resist obstruction or dislodging, and be simple to insert or replace" [4]. As in many cases, an ideal solution does not exist. Each of these tubes has its own unique characteristics (Table 29.1) and this make their use optimal in different clinical situations. Operative course and complexity of procedure and other added procedures, like endopyelotomy and opening of a calyceal diverticulum, mainly

dictate the choice of nephrostomy tube. We recently reviewed various drainage options after PCNL and would recommend this report to readers for further detailed analysis [10].

Utility of "mini-perc" percutaneous nephrolithotomy

A number of clinicians considered that the size of the nephrostomy tract and consequently drainage tube are important determinants of postoperative pain, bleeding complications, and hospital stay. The "mini-perc" technique uses a tract dilation up to 13F in adults [11] and 11F in children [12] instead of the 30F tracts and placement of 6–8F nephrostomy tubes and double-J ureteral stents at the end of the procedure. The mini-perc technique has shown excellent stone clearance rates, but the benefit of less postoperative pain has not been demonstrated. The reports were small retrospective series with no control population, smaller stone burden, and placement of both nephrostomy tubes and double-J ureteral stents. The added disadvantages of poor visualization of large stones with smaller caliber instruments [13] make it a less optimal technique.

In conclusion, "mini-perc" nephrolithotomy does not have any proven advantage to decrease pain or other postoperative complications when compared to traditional PCNL. It might have a role in children given the advantage of smaller incision and nephrostomy tracts, although there is no level 1 evidence to support this.

Small-bore nephrostomy tube

Maheshwari *et al*. prospectively compared placement of a 9F small-bore nephrostomy tube to a 28F nephrostomy tubes after routine 30F nephrostomy tracts [14]. Their results showed that patients with the 9F tubes had significantly lower analgesic requirements and duration of urine leak compared to patients with larger sized tubes. The 9F tube did not increase the risk of postoperative bleeding in these patients. In a randomized comparative study, Pietrow *et al*. demonstrated only a statistically insignificant trend towards decreased pain perception and analgesic requirements in patients with a 10F pigtail nephrostomy tube compared to patients who had a 22F Council-tip catheter as a nephrostomy tube [15]. They too did not find any adverse effect of using a smaller nephrostomy tube. Absence of power calculation and nearly 50% of their patients having supracoastal access might have been confounding factors.

Sixty patients undergoing PCNL in our institution were randomized into three groups based on technique of postoperative drainage: 24F re-entry nephrostomy tube, 8F pigtail catheter, and 16F Council-tip catheter with double-J stent. There was no difference in any post-

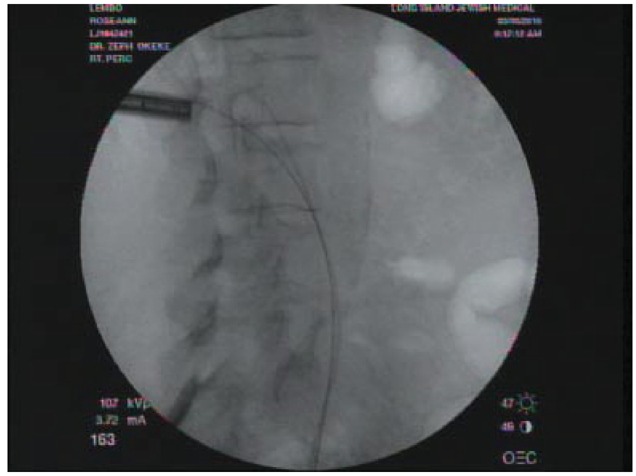

Figure 29.1 Placement of antegrade ureteral stent under fluoroscopic guidance.

operative complication, including bleeding, pain, or analgesic requirements. The group with the 8F pigtail catheter had significantly less urine leak when compared to the other two groups.

Smaller nephrostomy tubes may be advantageous in terms of pain control and analgesic requirements, but this has not been universally demonstrated. The size of the drainage tubes does not have any relation to the risk of postoperative bleeding in patients undergoing PCNL.

Stented percutaneous nephrolithotomy

Stented PCNL has primarily involved placement of a 6F double-J ureteral stent either antegrade or retrograde at the end of the primary procedure. This procedure was initially called tubeless PCNL, which is actually a misnomer. As reported by Monga *et al*., we prefer the term stented PCNL to tubeless PCNL, since these patients do have stents and hence are prone to symptoms from the stent tube as opposed to the nephrostomy tube [16]. Antegrade placement of a ureteral stent through the access sheath under fluoroscopic guidance is illustrated in Figure 29.1.

Stented PCNL was first reported by Bellman *et al*. in 1997 [17], challenging the routine use of a nephrostomy tube after PCNL. Although their study population was small, they reported dramatically reduced hospital stay, postoperative pain, and analgesic requirements; as hospital cost was halved, the authors had a very persuasive case for performing tubeless PCNL. A follow-up study by the same authors, with results for 112 patients – 86 undergoing isolated PCNL and 26 PNCL and endopyelotomy, showed a stone clearance rate of 93% and a UPJO resolution rate of 88% [18]. Although this study demonstrated wider application for tubeless PCNL, their study

population was highly selected. Their exclusion criteria were procedure lasting longer than 2 h, three or more percutaneous accesses, perforation of the collecting system, significant bleeding (not defined in the original paper), and the need for second-look nephroscopy.

Since these publications, there has been widespread interest in and enthusiasm for stented PCNL. Many authors have reported their experience with stented PCNL [19, 20] and there have been comparative studies between standard and stented PCNL [13, 21–23]. Some of these comparative studies [21] and other studies [24, 25] have also looked at stented PCNL versus small-bore nephrostomy tube placement after standard PCNL. More recent literature is available on the feasibility of stented PCNL in children [26], obese patients [27], supracostal access [28], patients with renal anomalies [29], and in an outpatient setting [30]. All these studies with stented PCNL had very strict inclusion criteria and the results are not applicable to all patients undergoing PCNL. These strict criteria include short procedures, uncomplicated procedures, minimum blood loss, no pelvic wall perforation, minimal tracts, complete stone clearance, and absence of need for second look. Although the safety and feasibility have been demonstrated by these studies in a select group of patients with strict inclusion criteria, there are no comparative studies demonstrating superiority of stented PCNL to traditional PCNL.

Feng *et al*. from Bellman's group compared traditional PCNL with wide-bore nephrostomy tubes versus "miniperc" versus stented PCNL, and reported best outcomes in patients undergoing stented PCNL, but this study is burdened by small sample size and significant patient selection [13]. Agrawal *et al*. reported a randomized comparison of standard PCNL with tubeless PCNL in 222 patients with similar restrictive criteria and a less than optimal randomization process; superior outcomes in terms of postoperative pain and hospital stay were reported for patients undergoing tubeless PCNL [22].

Problems with stented percutaneous nephrolithotomy

Desai *et al*. reported a three-arm study comparing standard PCNL drained with a 20F nephrostomy tube, standard PCNL drained with a 9F tube, and stented PCNL; best outcomes were for patients undergoing stented PCNL [21]. Although the authors did not observe any stent-related pain in their patients, they concluded that "small-bore nephrostomy drainage may be a reasonable option in patients who might have stent dysuria." Shah *et al*. attempted direct comparison of stented PCNL with small-bore nephrostomy drainage in a randomized fashion and reported less postoperative pain in the stented group [25]. They used a formal questionnaire in the immediate postoperative period and after discharge to evaluate stent-related discomfort. Nearly 40% of their stented PCNL patients had "bothersome stent-related symptoms" and around 60% of them had analgesia and/or antispasmodics to treat these symptoms. Choi *et al*. compared stented PCNL with tethered stents placed retrograde, aiding removal without a cystoscope, with 8F nephrostomy drainage after PCNL in a randomized study [24]. They concluded that both groups had similar levels of postoperative pain and length of hospital stay, but stent dislodgement was seen in 25% of the stented patients, almost exclusively in women. Although this high rate of stent dislodgement in this study may be attributed to the tether and the way it is secured, dislodgement is a significant problem in all stented PCNL and may necessitate secondary interventions.

Most of the literature comparing nephrostomy tubes and stents were performed in the setting of ureteral obstruction without percutaneous surgery [31]. Hence, they may not be equipped to compare nephrostomy tubes and ureteral stents in the setting of post-PCNL quality of life issues like pain, bother score, and dislodgement rate. At present, we could not find any study that addresses this specific question.

Tubeless percutaneous nephrolithotomy

Totally tubeless PCNL is in its very early stage of reporting in the literature. Goh *et al*. reported the first totally tubeless PCNL in 1999 by managing patients with ureteral catheters that were removed on postoperative day 1 [32]. The first true report of totally tubeless PCNL was by Karami *et al*. in 2004 [33]. Thirty patients who had a ureteral catheter inserted for PCNL and then removed at the end of the procedure (based on operative outcomes) were compared with 30 patients who had ureteral stents and nephrostomy tubes inserted after PCNL. They reported a significantly better outcome for patients without ureteral stents or nephrostomy tubes. Although this study has many flaws, like retrospective comparison, selection bias, and nonstandardized control group, it demonstrated the safety and feasibility of totally tubeless PCNL. More recent studies lend support to the totally tubeless PCNL concept [34]. The first randomized study was reported by Istanbulluoglu *et al*. in a selected population of patients undergoing PCNL [no serious bleeding or perforation in the collecting system during the operation, stone free or clinically insignificant residual fragments (<4 mm), and no more than one access], and compared totally tubeless PCNL with 14F Malecot nephrostomy tubes [35]. The same benefits of stented PCNL with regards to decreased postoperative pain and analgesic requirements, and reduced hospital stay were demonstrated in the totally tubeless PCNL group.

Totally tubeless PCNL may be applicable to a select group of patients who need PCNL, but further studies

Publisher's Note:

Figure 29.2 Classification of percutaneous nephrolithotomy patients and recommendations on exit strategy for renal drainage (reproduced from Srinivasan *et al.* [10]).

are needed to documents the benefit and safety of this procedure before any recommendations can be made.

Recommendations on renal drainage after percutaneous renal surgery (Figure 29.2)

• We recommend using a wide-bore nephrostomy tube for drainage after percutaneous resection of upper tract TCC.
• We recommend using a Council-tip catheter after lysis of infundibular stricture in patients with calyceal obstruction or after ablation of calyceal diverticulum.
• Patients undergoing PCNL, endopyelotomy, or both may have tubed or stented PCNL based on procedural complexity.
• There is level 1 evidence that "stented PCNL" decreases postoperative pain, analgesic requirements, urine leakage, and duration of hospital stay after percutaneous PCNL in a select group of "uncomplicated routine" patients, as defined by our previous study [4].
• The results of stented PCNL cannot be applied to patients who are at higher anesthesia risk (extremes of age have frequently been an exclusion factor, although stented PCNL in now being reported in children), or have more than two dilation tracts, congenital anomalies of the kidney (only case series of stented PCNL in horseshoe kidneys are available), residual stone fragments after procedure, renal pelvis perforation, excessive bleeding (arbitrary – not defined by any studies), other organ injury, preoperative sepsis. and presence of any other intraoperative complications. Hence, these should be considered exclusion criteria based on available evidence.
• We recommend tubed PCNL in all the above patients. The choice of a wide- or small-bore nephrostomy tube is left to the surgeon, although there is evidence that a small-bore nephrostomy tube may decrease postoperative pain and risk of persistent urinary leak. This benefit is without any increased risk of postoperative bleeding
• Currently, there is not enough evidence to recommend tubeless PCNL.

Hemostatic techniques after stented/tubeless percutaneous nephrolithotomy

In patients who are eligible for stented or tubeless PCNL, adjunctive techniques can be utilized to establish

hemostasis and aid parenchymal closure. Various options have been explored and these will be discussed below.

Sealants

Sealants are broadly of two kinds – fibrin- and gelatin-based products. The fibrin-based products are liquid agents that contain all essential components required for clot production, i.e. thrombin and fibrinogen. On contact with a tissue surface, the mixture of thrombin and fibrinogen forms a fibrin clot that aids in hemostasis and tissue seal. It is important to note that the fibrin sealants can seal independently of the patient's clotting factors. Gelatin-based products contain thrombin and gelatin. On contact with tissue surface, these products need the patient's own fibrinogen to start a clotting cascade. It has been reported that the gelatin particles aid in this process by providing a matrix for the formation of the clot. They reportedly swell in size by 19–400% and thus have a tamponading effect as well. A detailed review of the various types of sealants available on the market and their unique properties has been reported by Choe *et al*. [36].

The use of sealants after uncomplicated PCNL was first reported by Mikhail *et al*. in a randomized study comparing the use of fibrin glue to establish hemostasis and prevent postoperative complications to a control group [37]. They found no difference between the two groups with regards to postoperative hematocrit change and postoperative pain. The fibrin glue group did not have any increased incidence of postoperative complications. The study showed that use of fibrin glue is feasible in patients, but limited evidence for safety since long-term follow-up was not provided. A similar feasibility study was performed by Noller *et al*. in a small number of patients [38]. Shah *et al*. followed this evidence with a larger randomized study, with 31 patients undergoing uncomplicated stented PCNL in the study arm and 32 patients in the control arm [39]. The study group of patients had Tisseel (fibrin glue) inserted in the nephrostomy tract under fluoroscopic guidance. These patients had less postoperative pain and analgesic requirements compared to the control group, although there was no difference in the postoperative change in hematocrit or blood transfusion requirements. There was no difference in length of hospital stay or in postoperative complications, but again the data are limited due to short follow-up. Surgicel has also been reported in a small sample population to have no effect on postoperative outcomes [40].

Concerns regarding injection of glues into urothelial tracts have surfaced. Clayman *et al*. reported an *in vitro* study on the effect of hemostatic agents when they come in contact with urine [41]. Comparing fibrin sealant, gelatin sealant, Surgicel, and polyethylene glycol, the authors found that the fibrin sealants, Surgicel, and polyethylene glycol formed a gelatinous clot that was still present at the end of 5 days. Gelatin sealant, on the other hand, was suspended in urine as fine particles and did not form a clot that has potential for obstruction or other complications (Figure 29.3). It should be emphasized that there are no long-term studies on the safety of any of these agents when instilled into the urinary tract.

Figure 29.3 Gelatin sealant mixed in preparation for injection into the nephrostomy tract.

The above findings prompted the same group to investigate the use of gelatin sealant in sealing the nephrostomy tract with precautions to prevent free influx of this agent into the urinary tract. They reported on a technique of retrograde occlusion of the nephrostomy tract at the calyceal edge with balloon catheters, and under fluoroscopic guidance, injecting gelatin glue (FloSeal) into the nephrostomy tract [42].

The use of hemostatic sealant in percutaneous renal surgery is in its infancy. The optimal technique of application, agent of choice, and early and delayed complications need to be well charted before this can be recommended as effective management.

Thermoablative techniques

Electrocauterization has been extensively used in endoscopic urologic procedures and an adaptation of this technique to establish hemostasis was described by Jou *et al*. [43]. They reported using an elongated tip on a hand-held cautery device through the nephroscope and cauterizing individual bleeding points. In their series, 249 patients underwent uncomplicated stented PCNL and electrocautery was used to establish hemostasis in this population. Compared with patients who did not have electrocautery, those who did showed decreased need for blood transfusion after electrocautery of the

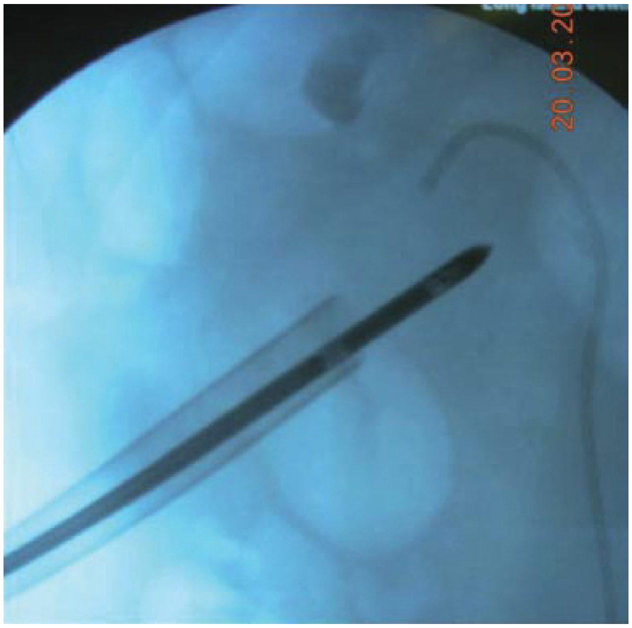

Figure 29.4 Cryoablation needle positioned in the nephrostomy tract under fluoroscopic guidance.

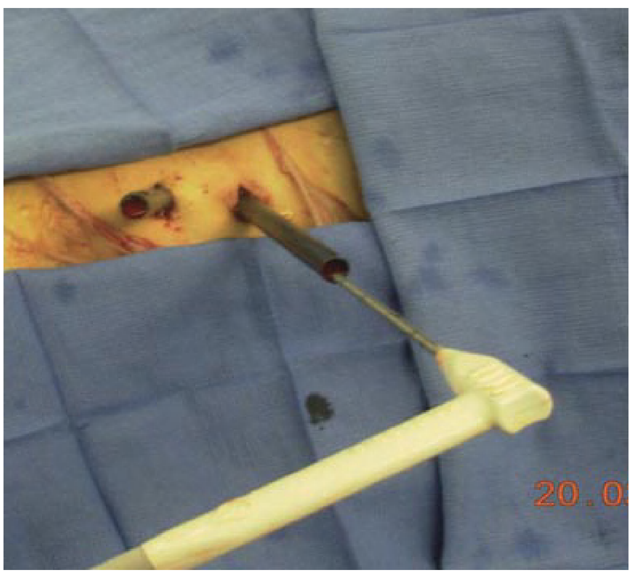

Figure 29.5 Cryoablation needle in position with the sheath pulled back out of the kidney to aid its contact with the parenchyma.

nephrostomy tract. Alternatively, a 26F resectoscope has also been used to electrocauterize the nephrostomy tract [42].

We have reported on the use of a cryofreeze technique to establish hemostasis [9] (Figures 29.4 and 29.5). We retrospectively compared patients after stented PCNL (no selection criteria), including those with multiple tracts, who underwent cryoablation of the nephrostomy tract after complete removal of all stone fragments, with patients who did not undergo ablation. A cryoprobe was positioned under fluoroscopic guidance and one freeze–thaw cycle was utilized to ablate the tract. Our results demonstrate that the cryoablation group had lesser bleeding complications, smaller incidence of urinary leaks, and shorter hospital stay. Although our study is limited by its retrospective nature, it is the first study to explore this technique in all PCNL patients, unlike other studies that have looked at uncomplicated PCNLs only.

Recommendations on hemostatic techniques after percutaneous nephrolithomy

- *In vitro* studies show a better safety profile for gelatin sealants.
- There is no evidence to attribute benefit in using hemostatic and tissue sealants after PCNL.
- No long-term data are available to evaluate the safety of these agents in the collecting system.
- Solitary studies support the use of thermoablative techniques (electrocautery or cryoablation of nephrostomy tracts) for hemostasis after PCNL. There is a paucity of data to make recommendations.

SECTION 3
Ureteroscopy

CHAPTER 33
Ureteral Anatomy

Dorit E. Zilberman
Department of Urology, Chaim Sheba Medical Center, Tel-Ha'shomer, Ramat-Gan, Israel

The normal ureter

The ureter refers to the hollow viscus that conveys the urine formed in the kidney to the urinary bladder. In the normal adult, the ureter is 25–30-cm (10–12 inches) long with a 4–5-mm caliber [1]. As it comprises the natural continuation of the renal pelvis, its beginning is defined at the ureteropelvic junction (UPJ), which lies posterior to the renal artery and vein [2].

The ureter runs caudal and medial in front of the psoas muscle, enters the bony pelvis, and terminates within the urinary bladder wall at the ureterovesical junction (UVJ). Its opening into the urinary bladder can be visualized endoscopically at the ureteral orifice.

For purpose of accurate location of various pathology along the course of the ureter and for further discussion or planning of certain interventional procedures, the ureter is arbitrarily divided into three segments [2]:

- Proximal ureter: relates to the ureteral segment that lies between the UPJ and the pelvic brim;
- Mid ureter: relates to the ureteral segment that is reflected over the sacral bone;
- Distal ureter: relates to the segment that lies between the lower border of the sacrum and the ureteral orifice.

An alternative nomenclature divides the ureter into the abdominal ureter, i.e. the segment that runs along the psoas muscle to the level of the iliac vessels ("*pars abdominalis*"), and the pelvic ureter, i.e. the segment that runs within the pelvic cavity from the level of the iliac vessels down to the urinary bladder ("*pars pelvina*") [1]. Some refer to these two segments as the proximal and the distal ureter, respectively.

Histology

From inside out, the ureteral wall consists of urothelial mucosa, lamina propria, muscular layer, and an adventitial layer. The last two layers are separated by a potential space, named Waldeyer [3]. The mucosal layer consists of transitional epithelial cells in close contact. The lamina propria contains collagen fibers and fibrocytes, as well as numerous blood vessels and unmyelinated nerves. The muscular layer consists of muscle bundles, with each bundle consisting of 50–100 cells. The bundles are separated by collagen fibers. Some muscle cells extend beyond one bundle to communicate with another, therefore maintaining the continuity of the muscular layer [3].

Traditionally, the muscular layer was described as consisting of three layers: an inner and an outer longitudinal layer separated by a circular layer of muscle fibers [1]. Yet, it appears that this configuration does not exist in the human ureter [3]. Instead, the arrangement of muscle fibers varies among different sites in the ureter, and overall the muscle bundles have a mesh-like appearance. In the abdominal ureter, the muscle bundles form helices and no layers have been identified under light microscopy. Within the pelvic ureter, the muscle helices show some degree of layering with an inner longitudinal and an outer circular orientation. In the

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

juxtavesical ureter, the inner longitudinal layer appears more prominent. The intravesical segment contains mainly longitudinal fibers, and the fibers of the roof shift laterally to join the bladder floor to build the trigone [3].

The adventitial layer of the ureter consists of bundles of collagen fibers, fibrocytes, nerve bundles, and muscle cells.

Blood supply and lymphatic drainage

The blood supply to the ureter originates from multiple arterial branches. The abdominal ureter is supplied by the abdominal aorta, renal artery, common iliac artery, and gonadal artery. The pelvic ureter receivess an additional supply from the internal iliac artery and its tributaries (i.e. vesical and uterine artery), as well as the mid rectal and vaginal arteries [2].

Of clinical importance to the urologist is the orientation in which blood vessels reach the ureter. The vascular supply to the abdominal ureter approaches anteriorly and medially, while the vessels supplying the pelvic ureter approach it posteriorly and laterally (Figure 33.1). Hence, laser incision of proximal ureteric strictures should be carried out in a lateral orientation, while laser incision of distal ureteric stricture should be performed medially.

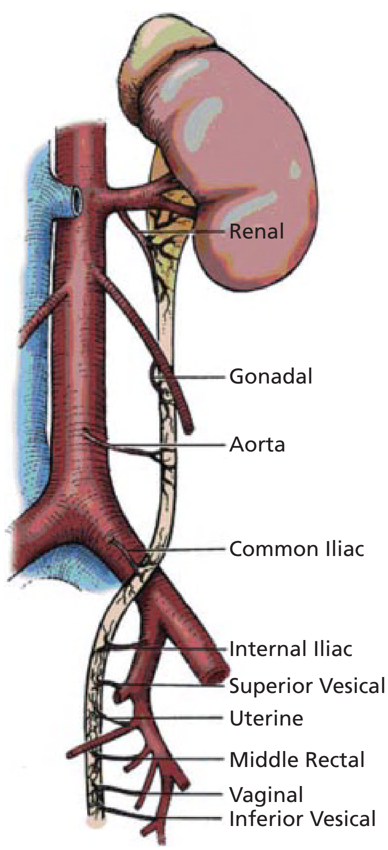

Figure 33.1 Ureteral blood supply (reproduced from Anderson *et al.* [2], copyright 2007, with permission from Elsevier).

Once the supplying vessels traverse the adventitial layer, they form an extensive arterial plexus along the ureter. This in turn protects the ureter when further mobilized for reconstruction purposes [2].

Lymphatic drainage of the ureter parallels its arterial supply. Lymphatic vessels originating in the pelvic ureter drain into the internal, external, and common iliac nodes. The left abdominal ureter is drained by the left para-aortic nodes, while the right abdominal ureter is drained by the right paracaval and inter-aortocaval lymph nodes [2].

Innervation

The lamina propria, muscular layer, and adventitia contain unmyelinated nerve fibers of adrenergic and cholinergic origins [3]. There is a controversy in the literature with regard to the presence of ganglionic cells in the ureter, as some investigators have demonstrated their presence in the pelvic ureter with associated dual adrenergic and cholinergic activity [4, 5], while others have failed to demonstrate this finding [3, 6, 7]. Consequently, ureteral neural activity was attributed to either action potentials originating within the ganglionic cells or to the myogenic nature of ureteral motility in which a stimulus is provided by a chemical mediator acting at a distance on the muscle cells or by the presence of a ureteral pacemaker [3]. Nevertheless, the neural activity continues following ureteral transection seen after ureteral surgery or after penetrating trauma.

Variants of the normal ureter

Ureteral medial deviation

Either bilateral or unilateral medial deviation of the ureter has been recognized as a normal variant of the ureteral course that can mimic medial deviation seen in retroperitoneal fibrosis. The incidence of medial deviation has been reported to vary between 15% and 18% [8], and is seen most commonly in young African–American patients [9]. Medial deviation appears to affect the right ureter more frequently than the left [8]. A possible explanation for this phenomenon is either pressure from adjacent vascular structures or psoas muscle hypertrophy [9].

Medial deviation of the ureter has been shown to occur most frequently at the level of L5–S1. At this level, the incidence of medial deviation was found to be as high as 11.2% in patients of Northern European descent versus 72% in patients of African descent with male predominance in both groups [8].

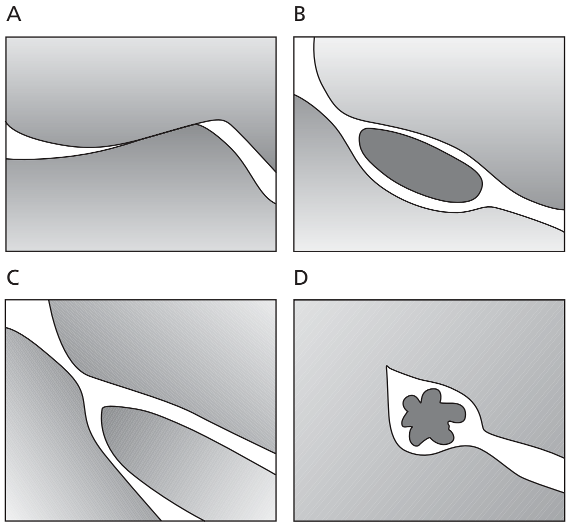

Figure 33.2 Ureteral orifice structures: A – normal cone ("grade 0"); B – stadium orifice ("grade 1"); C – horseshoe orifice ("grade 2"); D – golf hole orifice ("grade 3").

As opposed to the medial deviation seen in retroperitoneal fibrosis, there is no associated dilation of the associated upper collecting system in these patients.

Ureteral orifice: structure and position

The ureteral orifice of a single collecting system falls into one of four structural categories: cone orifice ("grade 0"), stadium orifice ("grade 1"), horseshoe orifice ("grade 2"), and golf hole orifice ("grade 3") (Figure 33.2) [10]. Moreover, there are three different positions where the ureteral orifice can be located within the urinary bladder: A, the normal position in the medial aspect of the trigone where the orifice is held firmly by a strong trigone; B, a moderate degree of lateral displacement; C, extreme lateral displacement (Figure 33.3) [10].

In a study of 671 orifices, 54% were of grade 0 type (cone shape), 23% were of grade 1 (stadium shape), 15% were of grade 2 (horseshoe shaped), and 8% were of grade 3 (golf hole). Vesicoureteral reflux (VUR) was noted to occur most frequently in grade 3 and C positioned orifices [10].

Physiologic narrowing of the normal ureter

There are three points along the ureter where physiologic narrowing is expected: at the level of the UPJ, at the crossing of the iliac vessels, and at the UVJ. These points are of clinical significance for two reasons: first, these are the most common places for urinary calculi to be lodged while passing; second, they may limit the passage of either rigid or flexible endoscopes and therefore warrant special attention [2].

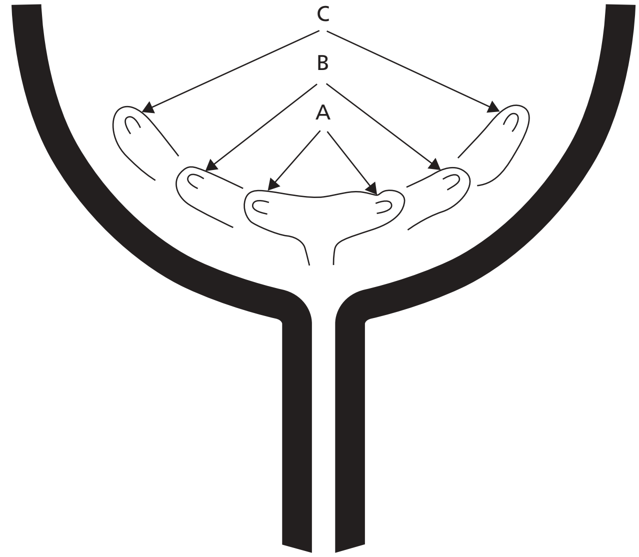

Figure 33.3 Ureteral orifice positions: A – normal position; B – lateral displacement; C – extreme lateral displacement (reprinted from Lyon *et al.* [10], copyright 1969, with permission from Elsevier).

When placing a ureteroscope through the UVJ, the tip of the endoscope should be positioned parallel to the ureteral orifice's lateral wall, in order to avoid tears. Hence, the scope should be rotated in parallel with the bladder's posterior wall before entering the ureter. It must also be remembered that the anterior angulation of the ureter, where it passes over the iliac vessels, as well as the posteromedial angulation where the ureter enters the true pelvis and courses behind the bladder, may restrict the passage of a rigid ureteroscope [2]. Care must be taken to prevent undermining of the ureteral wall, as well as transaction or avulsion of the ureter. Therefore, consider using a flexible ureteroscope to access the mid ureter if a rigid endoscope cannot be easily advanced.

Ureteral anomalies: special considerations

Ureteropelvic junction stenosis/obstruction

The term UPJ stenosis refers to a relative narrowing at the area of the UPJ that may result in ipsilaeral hydronephrosis, flank pain, and compromised renal function. This abnormality originates from a combination of reduced muscle fibers and an excess of collagen tissue that results in inhibition or normal peristaltic motion across this segment, hence causing an intrinsic obstruction [11, 12].Other reasons for intrinsic obstruction may be either valve-like processes or polyps [12]. Incomplete prenatal recanalization at the UPJ has been proposed by others [13].

Extrinsic obstruction at the level of the UPJ can be found as well, and associated findings include bands, fixed angulations, kinks, high insertion of the ureter, as well as crossing vessels [12].

The narrowed UPJ may allow the passage of wires or ureteral catheters, but not urine [11]. Passage of a superstiff wire to straighten any kinks at the UPJ and decompress the distended renal pelvis may be warranted [14].

Endoluminal intraoperative ultrasonography with a 6.2F 12.5-MHz catheter-based transducer has been offered as a tool for detection of periureteral vessels adjacent to the UPJ or the septum of a high-inserting ureter [15]. In a study comparing various means of identifying crossing vessels in patients with UPJ obstruction, the incidence of crossing vessels was found to be highest when using spiral computed tomography (CT) (79%), followed by endoluminal ultrasound (58%). Open surgery and angiography were found to be relatively inferior to the former two methods, identifying only 46% and 33% of crossing vessels, respectively [12].

In an outstanding study performed by Sampaio and Favorito, the vascular relationship to the UPJ was analyzed in an attempt to determine the safest location to perform endopyelotomy [16]. A close relationship between a prominent vessel (either artery or vein) and the anterior surface of the UPJ was found in 65.1% of cases and in 6.2%, a close relationship between a prominent vessel and the posterior surface of the UPJ. In 20.5% of cases, a vessel crossed lower than 1.5 cm above the posterior surface of the UPJ, and in 73.3% the posterior surface was free of vessels up to 1.5 cm above the UPJ. Given these findings, the authors recommended avoiding a posterolateral incision at the UPJ, as the safest location for endoscopic incision appears to be the lateral ureter. If the insertion of the ureter is high, the incision should be performed through the septum, between the ureter and renal pelvis [15].

Ureteroscopy in children: the "delicate" ureter

Performing ureteroscopy in the pediatric population is challenging due to a relatively delicate ureter, small ureteral orifice, tight UVJ, and large psoas muscles [17, 18]. The main concern in this population is that advancement of a working instrument may be unsuccessful or cause damage to the ureter [17]. It is therefore recommended that the smallest available instruments should be used, such as flexible 6.9F or 7.2F ureteroscopes with a 2F and 3.5F working channel, respectively, or a 6.9F or 9.4F semi-rigid ureteroscope with a 2F or 5.4F working channel, respectively [18]. Some also recommend balloon dilation of the UVJ [14] and others gradually dilating the ureter in order to avoid traumatic ureteroscopy [17, 19].

While the possibility of ureteral damage is real, most studies have suggested that ureteroscopic procedures in children are safe. A retrospective study analyzing ureteroscopy results in 71 children found that ureteral dilatation was necessary in only 30% of the cases and the preferred method was gradual dilatation using ureteral dilators, as they were believed to cause the least trauma to the intramural orifice [17]. This conclusion was supported by a later retrospective study analyzing the results of 31 ureteroscopies performed in children [19]; 10F calibration of the UVJ allowed easier ureteral access and limited the need for formal dilatation to only two cases.

Horseshoe kidney

This congenital anomaly results from an abnormal fusion of the metanephric blastema. As a consequence, there is a failure of ascent and rotation. The ureters of the fused kidneys are highly inserted and laterally positioned compared to the normal ureteral anatomy. In addition, they are draped over the renal isthmus, which results in an anterior deviation of their course, several centimeters below the UPJ [20].

Their tortuous course, especially when they traverse the isthmus, makes semi-rigid ureteroscopy for proximal ureteral or renal calculi remarkably difficult and potentially unsafe. Flexible ureteroscopes have been used quite successfully to manage proximal ureteral calculi or stones within horseshoe kidneys [21].

On the other hand, ureteroscopy for a mid or distal ureteral stone can be carried out safely and effectively and in a similar manner to that performed in case of a normal kidney [20].

Pelvic kidney

A pelvic kidney results from the failure of renal ascent and, similar to horseshoe kidneys, the associated ureter is highly inserted and malrotated [20].

The use of an access sheath may be necessary in order to "straighten" a tortuous ureter.

Given the pelvicalyceal anatomy, which places the renal pelvis anteriorly, flexible ureteroscopy may be indicated to access the proximal ureteral and renal collecting system [20].

Duplicated collecting system

A duplicated collecting system, either complete or incomplete, is the most common ureteral anomaly with an overall incidence of 0.8%.

In a completely duplicated system, the ureteral orifice related to the upper pole moiety opens into the urinary bladder in a more caudal and medial location compared to the normal one, while the ureteral orifice related to the lower pole system opens in a more cranial and lateral location (Weigert –Meyer rule) [22].

Ureteroscopy in a duplicated system does not differ from endoscopy of a normal system, yet some principles should be kept in mind:

- In case of complete duplication with two ureteral orifices or incomplete duplication with a single ureteral orifice, the correct ureter should be properly identified and intubated. Failure to do so is most common in cases of incomplete duplication, where the second ureter bifurcates within the intramural segment of the bladder [23].
- In case of incomplete duplication, retrograde injection of contrast should help identify the level of the bifurcation when direct visualization is difficult [23].
- In case of incomplete duplication with a single ureteral orifice, it may be necessary to dilate the orifice, and directly intubate the intramural ureter by direct vision after slowly withdrawing the ureteroscope to the appropriate level [23]. In the presence of UPJ obstruction in a partially duplicated system, individual anatomic variances should be expected, and a combination of antegrade and retrograde ureterography may be required for better demonstration of the entire system. Retrograde incision of an obstructed proximal ureter or UPJ may be feasible, though a combined antegrade/retrograde access may be required if retrograde ureteroscopy alone cannot be performed in the standard fashion [24].

Endoluminal ultrasound may be useful in these cases for the detection of crossing vessels or an internal communication between the two renal pelvices, and a holmium laser has been reported as a possible treatment option in this unique anatomic variant [25].

Ureterocele

This term refers to a cystic dilation of the distal ureter [22]. The incidence of this rare anomaly is 0.025–0.2%. The ureteral orifice entering the ureterocele may be stenosed to various degrees [23].

The orifice can be dilated once intubated, and ureteroscopy is then performed in the usual manner. Alternatively, a ureterocele may be entirely occupied by a large stone which may not allow the advancement of a guidewire up the ureter. In these cases it has been suggested to unroof the ureterocele with an electrocautery knife or holmium laser, along its inferior border, thus raising a flap of mucosa through which the stone is manipulated into the bladder and further fragmented. Following stone removal, ureteroscopic access is feasible as the ureter proximal to the ureterocele is often dilated to some degree.

Ureteral pseudodiverticula

This term refers to a 3–6 mm outpouching of the ureter [26, 27]. As its name indicates, ureteral pseudodiverticula (UPD) involves only the mucosa [27].It is detected incidentally during retrograde or excretory urography. To date, approximately 80 cases have been reported in the literature [26, 27].

This is an acquired ureteral anomaly caused by chronic urinary tract infection, and has been found to be highly associated with uroepithelial malignancy. One study found that UPD in patients with radiolucent filling defects or urinary tract stricture correlated with malignancy in up to 71% of cases. This anatomic variant appears to represent a clinical marker, antedating urothelial carcinoma by 2–10 years [27].

Ectopic ureter

This ureter does not terminate in the normal trigonal position but rather more caudally and medially, either in the bladder neck or the urethra [22]. This anatomic location makes uretereoscopic access challenging, given the unusual orientation of its orifice. Suggested manipulations to intubate an ectopic ureter are: (1) intravenous injection of methylene blue for exact localization of the ectopic orifice; and (2) in case of a stenotic or difficult-to-identify orifice, antegrade placement of a guidewire should allow appropriate localization of the ectopic ureteral orifice. Alternatively, the entire procedure could be performed in an antegrade fashion following the establishment of percutaneous access to the relevant collecting system [23].

The reconstructed ureter: special considerations

Urinary diversion

Ureterosigmoidostomy

Though uncommon today, ureterosigmoidostomy was considered in the past to be one of the first-line treatment options for bladder extrophy or following cystectomy, and remains the standard of care in places where appropriate stomal care is not available [28].

The main complications associated with this type of diversion that require an endoscopic intervention are urolithiasis or anastomotic strictures [28–31]. The ureters are typically implanted into a sigmoid pouch, but ureteral relationship to a major anatomic landmark is absent. Moreover, the typical case scenario in these cases is that the urologist who originally performed the diversion is not the same one who deals with the delayed complication [28].

Provided the ureteral orifice is identified within the sigmoid pouch, retrograde ureteroscopy is feasible in the standard manner [29], yet it is strongly recommended to percutaneously insert a guidewire to be advanced in an antegrade fashion across the anastomosis, and serve

as a through-and-through access [30]. This maneuver further aids in overcoming "unusual angles" to better delineate the anatomy during retrograde ureteroscopic access [28, 30, 31].

Feces has been noted to reflux into the collecting system during ureteroscopy; however, as long as proper drainage is maintained, this event should not lead to infectious complications. In addition to a nephrostomy tube, the preferred method of drainage is with a single-J biliary stent, which has multiple large side holes along its distal part, hence optimizing the drainage of both urine and feces [28].

Neobladders

Unique challenges have been identified with this type of urinary diversion. Often a retrograde approach to the implanted ureteral orifice is fraught with difficulty. Nonuniformity of the orifice location combined with mucosal folds often make identification of the ureteral orifices time-consuming, if not impossible.

In a Kock pouch diversion, the use of a flexible ureteroscope is strongly recommended, as the excessive torque required for a rigid endoscope to reach through an afferent nipple has the potential to injure the sphincter [31].

With a right colon pouch diversion, the delicate continence mechanism may be compromised using a standard cystoscope to identify the ureteral orifice. It would therefore be advisable to use an 8.5F ureteroscope instead [31].

In many orthotopic neobladder techniques, either one or both ureters are implanted into an afferent limb of bowel that extends from the reservoir. In such cases, identification of both the limb and associated ureters is crucial [32].

Direct visualization of the ureteral orifice requires flexible cystoscopy as access usually requires a "retroflexion maneuver." The ureter usually enters the reservoir at an oblique angle; therefore, the application of an angled-tip wire and a torque device may be useful to intubate the ureteral orifice [32].

Again, the key point in all these cases is placement of an antegrade guidewire through the collecting system down into the reservoir; it serves as a safety wire and a landmark when performing retrograde ureteroscopy.

Ureteroneocystostomy

The most common indication for this procedure is VUR in the pediatric population [33]. Reports of ureteroscopy performed on a reimplanted ureter have started to emerge as this pediatric population has entered adulthood, with an increased incidence of urolithiasis.

Ureteroneocystostomy can be divided into two broad categories: (1) that with relative preservation of the ureteral anatomy, e.g. the Glenn–Anderson procedure; and (2) that which significantly alters the course of the ureter as well as the location of the ureteral orifice, e.g. the Cohen technique [33].The Glenn–Anderson procedure is associated with repositioning of the ureteral orifice caudally and medially toward the bladder neck while preserving the normal course of the ureter [34]. The Cohen technique is associated with relocating the ureteral orifice to the contralateral side of the trigone in a submucosal tunnel [35].

Ureteral advancement using the Glenn–Anderson technique allows successful retrograde ureteroscopy, as well as stone fragment expulsion following shock-wave lithotripsy (SWL) due to the preserved straight course of the reimplanted ureter [33]. On the other hand, retrograde ureteroscopy following Cohen reimplantation is often impossible given the narrow angle between the endoscope and the reimplanted ureter [33, 36–40]. Possible maneuvers to overcome this problem include antegrade ureteroscopy [33]; antegrade percutaneous placement of an internal ureteral stent followed by retrograde urethral ureteroscopy [36]; percutaneous, needle-guided, transvesical trocar placement in direct alignment with the reimplanted ureter followed by transvesical retrograde ureteroscopy [37, 38]; and application of a 5F cobra-head catheter with the advancement of either a straight or angled-tip glidewire [39, 40].

Renal transplantation

Ureteral reimplantation during renal transplant results in an ectopic and anterior ureteral orifice, making its identification difficult [20].Nevertheless, retrograde ureteroscopy of a transplanted ureter can be successful with technique modifications [41, 42]. Intravenous indigo carmine is useful to identify the orifice. In addition, a flexible cystoscope as well as angled catheters (Kumpe or cobra) and angled hydrophilic glidewires may be useful for negotiating both the acutely angled transplanted ureteral orifice, as well as the frequently tortuous and redundant transplanted ureter [20].

Summary and conclusions

Whether the ureter has a classical or an unusual appearance, one should be familiar with both the normal and potential abnormal anatomy, as a result of congenital anomalies or previous surgical procedures. The anatomy of the ureter should never be overlooked when considering any type of endoscopic manipulation. Appropriate preoperative evaluation and intraoperative endourologic techniques should ensure proper, smooth, and usually successful endoscopic procedures.

CHAPTER 34

Rigid and Flexible Ureteroscopes: Technical Features

David A. Payne & Francis X. Keeley, Jr
Bristol Urological Institute, Southmead Hospital, Bristol, UK

Introduction

The natural progression from open surgery to everyday minimally invasive endourologic procedures is testament to the evolution and technologic advances that have brought about the modern day ureteroscope. From the humble beginnings where Young performed the first recorded ureteroscopy in 1912 using a 9.5F pediatric cystoscope [1], the past century has seen the progression and diversification of the endoscope into state-of-the-art ureteroscopes offering rigid, semi-rigid, flexible, and composite designs to perform upper tract diagnostic and therapeutic procedures. The introduction of fiberoptics paralleled by the progression of instrument technology has led to smaller, more maneuverable scopes with more acceptable ergonomic layouts. The latest generation of ureteroscopes now provides high-definition digital images of the ureter and intrarenal collecting system, allowing procedures to be carried out safely, with high success rates and minimal morbidity in adults and children.

To appreciate how ureteroscopes have evolved into their present day guise, this chapter begins with a summary of key technical developments, starting with the first acknowledgment of the endoscope, the effect of changes in instrumentation, and progressing through to the latest digital technology. A breakdown of key features of ureteroscopes is then given, discussing their similarities and differences before moving on to consider ureteroscopes currently available and potential future trends for their further development.

Rigid and semi-rigid ureteroscopes

Rigid ureteroscopes

Historical perspective

The history of the endoscope is well documented [2–4] and its consideration sets the scene for the progression to present day ureteroscopes (Table 34.1). The traditional components required to carry out a rigid endoscopic procedure are the telescope with working channels for irrigation and instrumentation, a light source, optics to convey the image, and a camera system to capture the image. The digital era is here and will eventually condemn the fiberoptic arrangement to the historical archives.

The forerunner of the endoscope can be traced back to 1806 with the construction of the light-guiding instrument or "Lichtleiter" by Phillip Bozzini for direct inspection of internal organs [5]. This scope was basic in design, consisting of a direct-vision hollow tube through which candlelight was transmitted by a mirror. The French surgeon Antoine Jean Desormeaux further developed the Lichtleiter, producing the "endoscope" in 1853 using a system of mirrors and lens, and a kerosene flame to provide light to examine the urethra and bladder (Figure 34.1). Gustave Trouvé further upgraded indirect illumination by candlelight to electrical illumination using glowing heated platinum wires at the tip of the instrument in 1873 [5]. The filaments were later

Table 34.1 Landmark evolutionary steps in the development of the rigid endoscope.

Year	Pioneer	Rigid endoscope and technologic advances
1806	Phillip Bozzini	German doctor who introduced the ""Lichtleiter" or light guiding instrument
1853	Antoine Jean Desormeaux	French surgeon who first introduced the "endoscope". Often considered as the father of endoscopy
1873	Gustave Trouvé	French inventor who moved the light source from outside to the inner tip of the endoscope and developed the "polyscope"
1879	Maximilian Nitze and Joseph Leiter	German urologist along with Viennese electro-optician Joseph Leiter are credited with the invention of the modern cystoscope
1960s	Several contributors	Introduction of fiberoptic cable enabling transmission of light from an external source
1960s	Harold Hopkins	British physicist filed a patent for the "rod–lens" system that was later adopted by Karl Storz in 1965

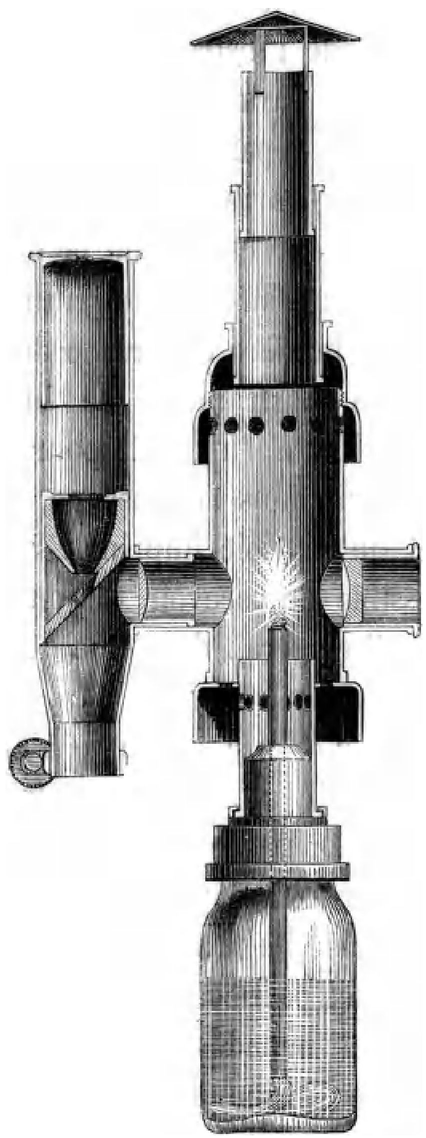

Figure 34.1 Antoine Jean Desormeaux modified the "Lichtleiter" to produce the 'endoscope'. From *De l'endoscope* by A.J. Desormeaux, 1865 (courtesy of Wellcome Library, London, UK).

replaced by Edison's incandescent light bulb. The Nitze-Leiter cystoscope, a rudimentary version of the modern cystoscope, was constructed in 1879, incorporating a simple lens system into the viewing tube [5].

The introduction of fiberoptic lighting in the 1960s replaced the incandescent bulb, revolutionizing the manufacture of rigid endoscopes. The design was based on the principle of total internal reflection; when light travels in a transparent medium such as glass, internal reflection of the light occurs at the interface between the medium and its surroundings, as demonstrated by John Tyndall in 1854 [6]. This physical property of internal reflection allows the "bending" of light within flexible glass. Thus, light travelling inside a small-diameter flexible glass fiber surrounded by cladding of lower refractory index can be transmitted over a long distance with minimal degradation. The benefit of modern fiberoptic lighting is greater illumination by cooler light, ultimately making it safer. An additional benefit is that the scopes can be made with a smaller-profile shaft, allowing more room within the shaft for the addition of an irrigation and instrument channel. The fiberoptic cable is often attached via a light post to the endoscope, but may alternatively be built into the design of the scope.

The innovative work of the British physicist Harold Hopkins led to the next major breakthrough in rigid endoscopic design with the introduction of the rod–lens system in the 1960s [7]. Until then, the shaft of the scope consisted of a hollow tube with a series of thin relay lenses separated by long air spaces. The relay lenses had to remain in precise alignment and any displacement of the lens resulted in a significant loss of image transmission. There was also a significant loss of light transmission with this system. Hopkins replaced the thin relay lenses within the shaft of the endoscope with long, contoured glass rods acting as the transmission medium, whilst the thin pockets interspersed between the glass rods acted as lenses. With the telescope primarily being

made of glass, which has a higher refractive index than air, light transmission could be increased ninefold over previous lens systems, with the additional benefit of reduced image distortion and a wider viewing angle. The outer diameter of the endoscope shaft could also be reduced, paving the way for the development of the rigid ureteroscope and the introduction of working channels. The old lens system was notorious for its lack of durability and the Hopkins rod–lens system produced a significant improvement in this area. There were a few apparent weaknesses in the rod–lens design: any deviation in the use of the cystoscope from being used in straight lines, as can occur with the application of torque to the shaft, could lead to misalignment of the rod–lens set up and the permanent disappearance of up to half the image. The problem manifests itself as a half-moon or crescent-shaped defect when viewing through the scope eyepiece. This design flaw would be seen to be disadvantageous in the passage of the endoscope through the natural undulations of the ureter. A further consideration for ureteroscopic design centers on the diameter of the lens that dictates the size, or degree of magnification, of the image; the reduced diameter of the ureteroscope would inadvertently have a smaller image than the larger cystoscope.

Endoscopic evolution

Considering that Young undertook the first recorded ureteroscopy in 1912, it was another 65 years before Goodman [8] and Lyon *et al*. [9] ventured into the ureter, performing distal ureteroscopy in both male and female patients (Table 34.2). Goodman reported using an 11F pediatric rod–lens cystoscope to inspect the distal ureter in three adults [8]. In one of these patients, a distal ureteral tumor was fulgurated, marking the first ureteroscopically treated tumor. Lyon *et al*. reported ureteroscopy in five adults using Jewett sounds for ureteral dilation before passing an 11F pediatric cystoscope [9]. Most of these early ureteroscopy patients were women. Lyon *et al*. reported in 1979 the use of specially designed ureteral dilators attached to the tip of a flexible probe. They were able to dilate the orifice to 16F, permitting insertion of a standard length 13F cystoscope for distal ureteroscopy in men. These early investigators demonstrated the ease and safety of rigid ureteroscopy for the distal ureter in both sexes.

The first rigid ureteroscope specifically designed for ureteric use was produced in 1979 by Richard Wolf Medical Instruments and was modeled on a pediatric cystoscope. Lyon *et al*. reported its clinical use [10]. This 13F instrument had a working length of 23 cm, and sheath sizes of 14.5 and 16F, and a 16F resectoscope sheath were also available. The 13F sheath was used only for inspection, but the larger sheaths allowed simultaneous passage of a ureteral catheter or basket for stone manipulation and removal. For the first time, ureteral calculi were visualized, engaged in a basket, and removed [10, 11]. A longer ureteroscope that could reach all the way to the renal pelvis was developed by Enriqué Pérez-Castro in collaboration with Karl Storz Endoscopy, and its use was reported in 1980 [12]. Its 39-cm length allowed inspection of the renal pelvis for the first time. Initially hampered by the rod–lens system and size of shaft, other endoscope manufacturers quickly followed suit.

Further uerteroscopic modification was not due to advances in scope technology, rather the introduction of and progression in instrumentation. The launch of ureteroscopic ultrasonic lithotripsy for the treatment of urolithiasis would lead to modifications in ureteroscopic configuration. Initially, the probes were hollow and 8F in diameter, requiring removal of the telescope and blind stone lithotripsy, before being replaced by smaller solid probes that could pass through the working channels. These smaller probes (1.5–2.0 mm) were too rigid to negotiate the angles of the instrument working ports, and this led to the development of the offset eyepiece

Table 34.2 Landmark evolutionary steps in the development of the rigid ureteroscope.

Year	Pioneer	Rigid ureteroscope technological advances
1977	TM Goodmanand Edward Lyon	Provided the first reported series of distal ureteroscopically performed cases
1979	Richard Wolf	Credited with the design and construction of the first rigid ureteroscope
1980	Enriqué Pérez-Castro	Developed the “long” ureteroscope in collaboration with Karl Storz Endoscopy
1980	ACMI	The Rigiflex was the first ureteroscope to adopt the use of fiberoptics to allow the “gooseneck” eyepiece
1989	Huffman	Produced the 8.5F “compact ureteroscope” with a 3.5F-working channel. The rod–lens was integrated into the ureteroscope

which allowed the direct passage of the probe through a straight working channel under direct vision. Rigid ureteroscopes were later designed with an interchangeable offset eyepiece and standard telescope, allowing easier passage of the scope. Due to difficulties and complications from inserting rigid rod–lens type ureteroscopes with diameters approaching 14.5–15F, it became apparent that smaller ureteroscopes were needed. With the availability of smaller working instruments, Huffman described a compact ureteroscope that was 8.5F in diameter and had a working channel of 3.5F [13]. The rod–lens telescope was integrated into the ureteroscope, which helped decrease the outer diameter while maintaining a good-sized working channel.

General properties

The rigid ureteroscope has not deviated significantly from the original pediatric cystoscope used to inspect the ureter. Any development has centered on the improvement in the light source, the introduction of the rod–lens optics system, the launch of a single working channel, and changes in the overall ureteroscope dimensions. That said, over the years the ureteroscope has become narrow enough to ensure easier ureteric access and long enough to venture into the renal pelvis, and has a working channel to allow instrumentation for intervention and diagnostic purposes.

Optics, angle, field of view, and eyepiece

The rod–lens systems has provided excellent optical quality over the years, but scopes incorporating this design tend to have larger diameters and are prone to damage following angulation of the ureteroscope. The "angle of view" in an endoscope can vary from 0º, providing a straight view of the structure in question, to 70º, which allows inspection of tissues at an oblique angle from the straight axis. These rod–lens ureteroscopes were either interchangeable (from 0 to 70º angle of view) or integrated within the ureteroscope itself. The 70º lens was primarily used to inspect the renal pelvis and calyces, although these lenses are now virtually obsolete with the development of flexible ureterorenoscopes. The few current rod–lens ureteroscopes have integrated telescopes because of their smaller size advantage, and the angle of view through the objective lens is fixed at 0–5º. The advantage of a slight angulation on the direct vision lens is easier and quicker visualization of working instruments being passed out of the tip, reducing the potential for inadvertent iatrogenic injury to normal urothelium. The "field of view" is often quoted for ureteroscopes and is the entire view seen by the eye when it is trained in any particular direction. For endoscopes, this can vary from 60º to 90º, depending on the type of instrument.

Initially, ureteroscopes had a standard eyepiece design, which sees the ocular lens drawn in a straight line through the shaft of the scope. When rigid ultrasound probes were first introduced for ureteroscopic lithotripsy, an offset ocular configuration was trialed that allowed for direct access to the instrumentation port, allowing easy entry and removal of rigid accessories without impairing the view of the scope. Most companies went on to introduce offset eyepieces that were either fixed or movable.

Dimensions and sheath tip

From the earliest days of ureteroscopic evolution, the diameter of the rigid scope has come down from 16F to 8.5F, whilst the length of the scope ranges from 25 to 54 cm, allowing the length of the ureter to be accessed along with the renal pelvis. Early ureteroscopes had beaked tips emulating early cystoscopes, and on introducing the scope into the ureteral orifice, advancement could result in ploughing of the ureteral epithelium. Most current tip designs are beveled to provide safer and easier advancement into the ureter (Figure 34.2).

Working channel

The single channel in most rigid ureteroscopes varied in size from 3.5 to 5F, a range dictated by the size of the largest of instrumentsavailable at the time. The working channel was triangular in cross-section and allowed irrigation to continue around the sides of any deployed instrument within. Ureteroresectoscopes incorporated manually working elements much like standard transurethral resectoscopes. Working elements included resecting loops, cold and hot knife blades, and fulguration electrodes.

Semi-rigid ureteroscopes

Endoscopic evolution

Offering a different solution to the interchangeable offset eyepiece, the Rigiflex ureteroscope by ACMI was introduced in 1985. The eyepiece could be straightened for introduction into the ureter and later offset to admit the ultrasonic lithotripter. The ACMI HTO-5 was unique in being the first ureteroscope to incorporate fiberoptic imaging technology to produce the flexible "gooseneck" eyepiece. Although the scope had a 12.7F diameter shaft and a 5F single working channel, comparable rod–lens ureteroscopes of the time with a 5F channel were 14.5–15F in size.

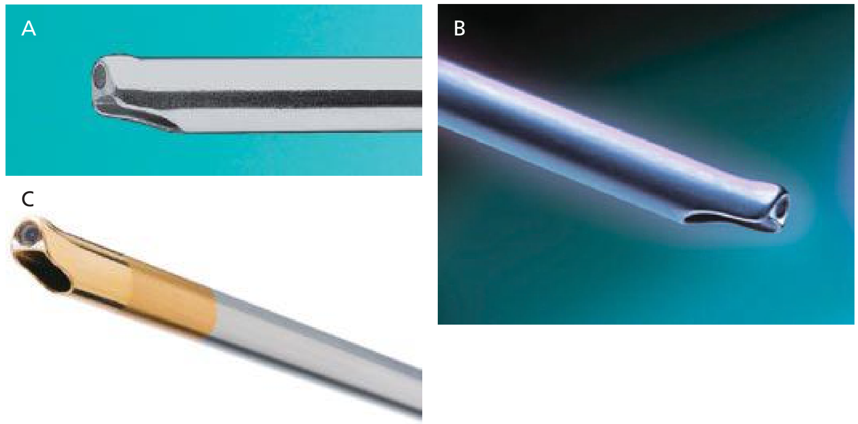

Figure 34.2 Ureteroscope atraumatic distal tip as seen on (A) Storz, (B) Wolf, and (C) Olympus scopes. The tips generally come beaked, beveled, or flat, as each manufacturer argues a case for easier atraumatic negotiation of the ureteric orifice (courtesy of Karl Storz, Richard Wolf, and Olympus Medical, respectively).

Ureterorenoscopy with a rigid scope still had inherent problems with the rod–lens optics due to the tortuous nature of the ureter and the caliber and working length of the instrument, which gave impaired vision. With the growing demand for rigid ureteroscopes in the 1980s, the further use of fiberoptic technology would enable further miniaturization of the shaft diameter along with reduction in size of the working channels. The "miniscope" or semi-rigid ureteroscope combined smaller working channels and fiberoptics, allowing both illumination and image incorporated into a metal sheath. The optical system was reduced in size compared with the rod–lens design, leading to its primary advantage, an overall reduction in the outside diameter of the scope, but not at the expense of reducing the size of the working channels.

Although the rigid rod–lens system provided excellent optical quality, an additional advantage of the miniscope was that the fiberoptic bundles within the metal shaft could be flexed significantly without distortion of the image and the appearance of a dark crescent-shaped area that can occur with excessive torque applied to the rod–lens telescope. Such flexibility allows easier passage of the scope through the intramural ureter and then anteriorly over the iliac vessels with great maneuverability to negotiate narrowed or strictured ureters. Other advantages of the miniscope included easier access, reduced requirement for ureteric dilation, and decreased ureteric injury.

The first available "miniscope" was Candela Laser Corporation's semi-rigid ureteroscope, as described by Dretler and Cho in 1989 [14]. It was the first to incorporate two independent working channels, one for an accessory and one for flow, each of 2.1F size. It was the success of this 41-cm instrument with a 7.2F distal section that established it as the benchmark instrument of its time and prompted other US manufacturers to develop competitive instruments of similar design, such as the MR-6 ureteroscope from ACMI. The MR-6 proved to be much more durable than the Candela scope and quickly gained supremacy [15]. It had a sub-7F distal section with larger throughput capacity of one 2.3F and one 3.4F device in separate channels. The final distal shape was determined by enclosing the smallest size optical system the engineers could conceive at the time, along with the two separate throughput channels in a triangular-shaped outer tube, giving a 6.9F distal section. For the image system, by designing a conventional glass objective coupled to a 0.5-mm diameter fused quartz fiber bundle, more individual pixels of optical information were provided than the etched glass fiber bundle in either the Candela or the HTO-5 scopes. It came in a short 33-cm length version to allow access to the distal ureter and up to the ureteropelvic junction (UPJ) of females. The MR-6L was 41 cm long and was intended for use in males and obese patients. Over the past decade, miniureterosopes or semi-rigid ureteroscopes have been refined in terms of materials, ergonomic layout, fiberoptics, and camera systems, though there has been no really significant steps forward in scope evolution. They still remain the most commonly used type of ureteroscope [16].

General properties

Optics and eyepiece

In practice, the rod–lens ureteroscope, although offering quality images, allows only limited vertical deviation on advancement and is suited to ureteral sorties where the scope undergoes minimal change in direction. The introduction of fiberoptic bundles within a rigid shaft has enabled navigation through the more challenging tortuous ureter without leading to optical malfunction. Although earlier fiberoptic image bundles were disadvantaged by a characteristic graining effect, the pixel density in most current semi-rigid ureteroscopes has now increased beyond 30 000, such that the images are

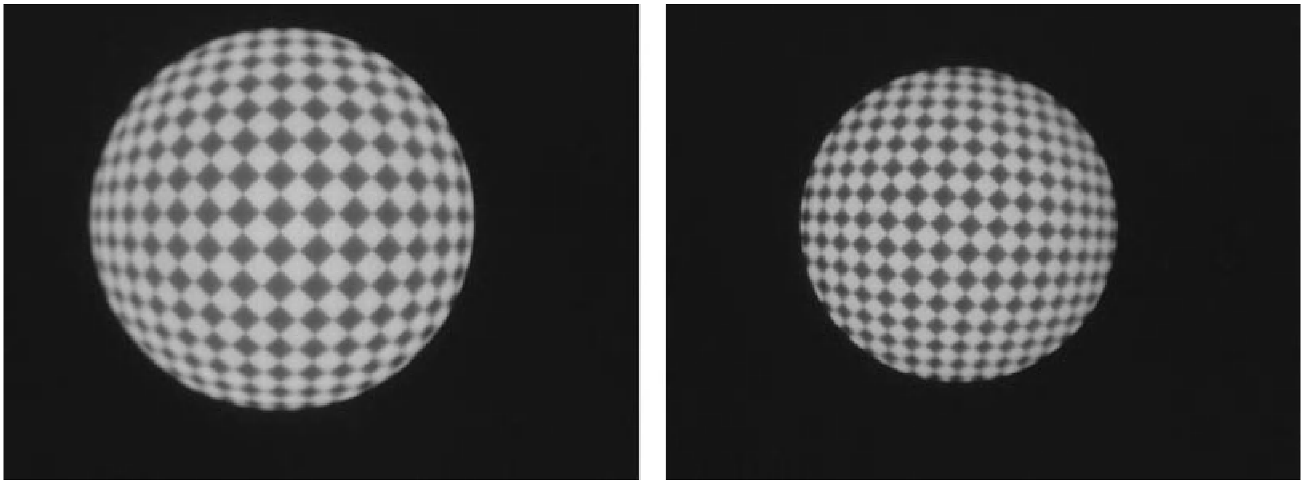

Figure 34.3 The latest improvements in bundle density mean the image size can be increased without compromising quality (courtesy of Richard Wolf).

large and bright and are much closer in quality and size to those of the traditional rod–lens system (Figure 34.3). Newer fiber-packing techniques and advanced camera systems have led to further improvement. Fiberoptic systems now provide light and image transmission through most current semi-rigid ureteroscopes.

As discussed earlier, offset eyepieces became necessary when rigid ultrasound probes were developed for ureteroscopic lithotripsy. These probes, as well as larger more rigid working instruments, required a straight working channel for passage through the scope. Offset eyepieces can either be fixed or moveable (Figure 34.4) and can be either angled or offset, although always straight and parallel to the ureteroscope shaft. The angle of view is usually 0–5°.

Dimensions and sheath tip

It is important for ureteroscopic design and procedural success that the scope is narrow and flexible enough to deal with the changing caliber of the ureter, with areas of natural lumen reduction at the UPJ, iliac vessels (12F), and vesicoureteric junction (3–10F), along with potential pathologic narrowing. Instrument manufacturers have made attempts to reduce the trauma of insertion by modifying shaft design and manufacture. The miniureteroscope shaft has a graduated stepless design, starting with a distal tip diameter as small as 6.9F [15], which rarely requires predilation of the ureteric orifice and intramural ureter, rising up to 13F in the larger scopes. This ensures maximal proximal strength of the scope whilst providing a gradual dilation of the ureter as the scope is advanced. The continued reduction in ureteroscope diameter has led to a reduction in the number of ureteral strictures seen and an increased success rate for the procedure [17]. Furthermore, the profile of the semi-rigid ureteroscope tip is designed to ensure minimal iatrogenic damage to the ureteric orifice and urothelium whilst maximizing the successful passage of the ureteroscope into the ureter (see Figure 34.2). Most of the currently available miniureteroscopes are beveled for easier advancement and have a round or oval tip design; however, scopes with smooth triangular tips have recently become available. The semi-rigid ureteroscope is generally manufactured in two lengths. A "short" ureteroscope of just over 30 cm can be used to access up to the level of the mid ureter in males and renal pelvis in females. To reach the renal pelvis in a male requires a "long" ureteroscope of 40 cm or more.

Working channel

Advances in construction of the miniscope led to the option of either a larger diameter single working channel with one large space for both irrigation and instrumentation to run through, or two separate working channels allowing separate instrumentation and irrigation (Figure 34.5). A larger single channel permits the use of larger instruments and possible removal of small stone fragments or biopsy specimens through the sheath, and dual instrumentation depending on the limits of each channel port. Two separate channels allow the operator to work through one channel without impeding irrigation flow through the other. The diameters of the two separate working channels range from 2.1 to 5.4F, but are usually 3.4F, allowing the introduction of a more rigid 3F instrument and 2.4F for irrigation or a second accessory. The channels are either triangular or oval in cross-section, which allows irrigation to continue around the sides despite the placement of an accessory instrument.

Figure 34.4 The Wolf E-Line series demonstrates the available eyepiece designs. These facilitate both easy insertion under direct vision with the (A) standard design, as well as the ability to use the straight rigid accessories in comfort with the (B) lateral and (C) oblique offset designs (courtesy of Richard Wolf).

The introduction of holmium laser lithotripsy for the treatment of upper urinary tract stone disease in 1996 [18] was a huge step forward in endoscopic stone treatment, and is now the bedrock of contact lithotripsy in most departments. With fiber diameter measuring only 200 and 365 μm, this has virtually abolished the requirement for anything larger than a 3.4F channel, allowing smaller outer diameter ureteroscopes to be used with better flow and therefore better vision. The narrow lasers also allow them to be used simultaneously with another accessory down a working channel, while still maintaining some flow.

Camera and video systems

Image transmission has evolved in line with changes seen with the semi-rigid ureteroscopes. Although images are occasionally viewed directly from the eyepiece due to technical problems or, rarely, the surgeon's preference, it has been conventional for some years to use indirect imaging on a television monitor using a video system. The video camera and monitor-based endoscopes allows binocular vision that is projected onto a large television monitor; this is ergonomically easier for the urologist and also can be enjoyed by the theater team. The high-resolution image output has also reduced the discrepancy between the better images obtained with the larger endoscopes compared with those previously seen with the ureteroscope.

Analog images produced by transmission down fiberoptic bundles continue to be the main pathway to deliver views of the subject matter to the camera in the majority of semi-rigid ureteroscopes. The drive to engineer semi-rigid ureteroscopes with digital distal sensor

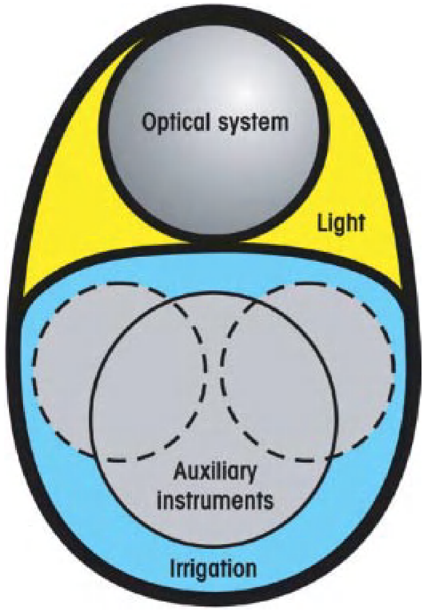

Figure 34.5 Possibilities available with single large- or twin-channel scopes with irrigation maintained (courtesy of Richard Wolf).

chip technology to produce high-quality digital images has not yet taken off to the same degree as seen with the flexible scopes. This is partly due to the high density of fiberoptic bundles that can be incorporated into the semi-rigid ureteroscope, which are more resistant to image degradation when compared to those found in the flexible ureterorenoscope. Olympus, however, produce the only digital semi-rigid ureteroscope, called the EndoEye video ureteroscope and also known as the Oes Pro Video, which has a distal charge coupled device (CCD) video chip (seeTable 34.3).

Irrigation

An effective irrigation system is important to optimize the chance of access into the ureteric orifice and provide good visibility during either rigid or flexible ureteroscopy. The simplest arrangement involves gravity irrigation, which has to contend with the small diameter and long length of the ureteroscope causing a reduction in flow. Other configurations are available that generate a greater pressure and therefore flow, with the pneumatic sleeve applied around the bag of fluid being the most common semi-automated set-up. Devices requiring operator/assistant input to supply increased flow on demand include attaching two 60 mL syringes via a Y-connector to inject irrigation as needed, and the Peditrol irrigation device that delivers a bolus via a foot pedal [19]. Automated infusion systems offering continuous saline irrigation, such as the Ureteromat, also exist which require no input from the endoscopist. The newly developed continuous-flow ureterorenoscope (10.5F) promises to provide a 100 times higher flow capacity whilst preserving the intrarenal pressure compared with conventional ureteroscopy *ex vivo* [20].

Current ureteroscopes

Rigid ureteroscopes are available in many of the designs previously described. The characteristics of the latest designs of currently available semi-rigid ureteroscopes are given in Table 34.3.

Care, maintenance, and technical failure

An important consideration when weighing up the purchase of a new ureteroscope is its longevity and often a balance is sought between optimal duration of scope life and its efficacy. Although less of a problem with the semi-rigid ureteroscope in comparison with its flexible counterpart, applying excessive torque causing deflections over 5 cm can lead to significant image distortion and scope failure. The majority of ureteroscopic failures are attributed to iatrogenic causes, including improper handling at the time of instrumentation and problems during the sterilizing process [21]. Regardless of the type and make of ureteroscope, the frequency of repair increases with decreasing ureteroscope diameter and increasing length of instrument [22]. Previously, with stepped shaft design of the rigid ureteroscope, bend stress was concentrated at solder points. Newer tapered shafts were produced to reduce this problem, making them more durable and less traumatic. Other notable risk factors for predicting the number of uses expected from a ureteroscope are its age and whether the ureteroscope has undergone comprehensive repair as a result of prior damage [21]. For optimal scope life, it is important that optimal care is taken in looking after the instrument and cleaning procedures are carried out with strict adherence to company instructions.

Flexible ureteroscopes

Flexible ureteroscope versus rigid ureteroscope?

Flexible ureterorenoscopy has developed rapidly over the past 30 years as technologic improvements have been made in both instrument size and design. Advances in fiberoptic technology, improved deflecting mechanisms, and a greater diversity of working instruments, have all increased the utility of the flexible ureterorenoscope in the diagnosis of upper tract disorders. This has led to ever-increasing indications for minimally invasive diagnostic and therapeutic interventions. Over the same time frame, the number of ureteric complications

associated with ureterorenoscopy has significantly decreased [23, 24]. Although differing significantly in cost and complexity, the flexible ureterorenoscope should not be considered as a separate entity from the semi-rigid ureteroscope. Both types of ureteroscope are in fact used in a complementary fashion to access, inspect, and treat pathology in the entire upper urinary tract collecting system [25]. So complementary, in fact, that it is common practice to first use the semi-rigid ureteroscope with its graduated increase in diameter to optically dilate the ureteral orifice and lower ureter, both to ease passage of the flexible scope and increase the longevity of the delicate smaller caliber flexible ureterorenoscope. The rigid ureteroscope is therefore ideal for managing pathology in the lower aspects of the urinary tract, whereas the flexible ureteroscope is better suited to the upper ureter, renal pelvis, and calyces. Using active tip deflection, the flexible ureterorenoscope is able to negotiate the angulations of the ureter and pass safely beyond the iliac vessels before being advanced all the way up to the intrarenal collecting system under direct visual control.

Flexible endoscope development

Fiberoptic endoscope

The existence of the flexible endoscope owes a great deal to the development of fiberoptic technology, the principles of which were developed over a century ago by John Tyndall (Table 34.4). Based on the physical properties of light [6], small-diameter transparent glass fibers when bundled randomly will uniformly transmit light from one end to the other (even when bent), but no image. The use of glass fibers in a "noncoherent" arrangement to provide illumination was soon followed by the introduction of fibers bundled together coherently and with identical orientation at either end. These dots of light coalesce to transmit images [26] to the eyepiece (Figure 34.6). The view seen is therefore made up of thousands of images from each individual fiber to produce a composite matrix image. In the 1950s, Harold Hopkins designed the "fiberscope," a coherent bundle of fibers with the ability to transmit images [27]. It was not however until 1957 that the South African physician Basil Hirschowiz created a diagnostic flexible endoscope that was fit for clinical practice. Using superior glass fiber technology, the potential of his invention was soon realized by several medical specialities, and flexible endoscopy was in widespread use by the mid-1960s.

Subsequent improvements in fiberoptic technology have allowed the bundling together of greater numbers of fibers, along with a second layer of glass cladding that has a different refractive index from the core of glass. This design is much more durable than the previous uncladded designs. The interface between these two different glasses produces the internal reflection [6, 28], resulting in the production of a sharper image with better illumination. The additional cladding does not, however, transmit light and causes a mesh-like or honeycomb appearance of the image, known as the Moiré effect. The advances in fiberoptics have not only produced superior images, but have also enabled a reduction in instrument size, allowing for both larger working channels and a smaller outer shaft diameter. Further modifications to the endoscope have allowed its tip to be actively manipulated by the endoscopist along with the development of instrument channels.

Digital endoscope

The image quality with the fiberoptic endoscope is limited by the finite diameter of the image-carrying glass fibers, leading to the pixelated "chicken wire"

Table 34.4 Landmark steps in the evolution of the flexible endoscope and ureteroscope.

Year	Pioneer	Flexible endoscope and ureteroscope technologic advances
1854	John Tyndall	Noted that when light travels in glass, internal reflection of the light occurs at the interface between that medium and its surroundings
1950s	Harold Hopkins	Designed a "fibroscope," a coherent bundle of flexible glass fibers able to transmit an image
1957	Basil Hirschowiz	Using a superior glass fiber for the flexible endoscope resulted in the first clinically practical endoscope
X1960	Marshall	Used a 9F flexible fiberscope to visualize the renal pelvis to inspect for calculi
X1962	McGovern and Walzak	Used a 9F passive, channel-less flexible fiberscope to visualize an impacted ureteric calculus
1971	Takagi *et al*.	First clinical use of an actively deflectable fiberoptic ureteroscope for the visualization of the urinary tract
X1970	Boyle and Smith	Created the charge coupled device (CCD) – a chip that can store data in the form of electric charges
1983	Bagley	Introduction of a passively deflectable flexible ureteroscope with combined irrigation and working channels
1994	Grasso	Reported the use of a new two-way deflecting 7.5 F flexible ureteroscope with active and passive deflection
2005	ACMI Digital Endoscope	First commercially available digital sensor endoscope brought into production with a lighter more ergonomic design
2006	ACMI Digital Ureterorenoscope	First commercially available digital sensor ureteoscope brought into production with a lighter more ergonomic design

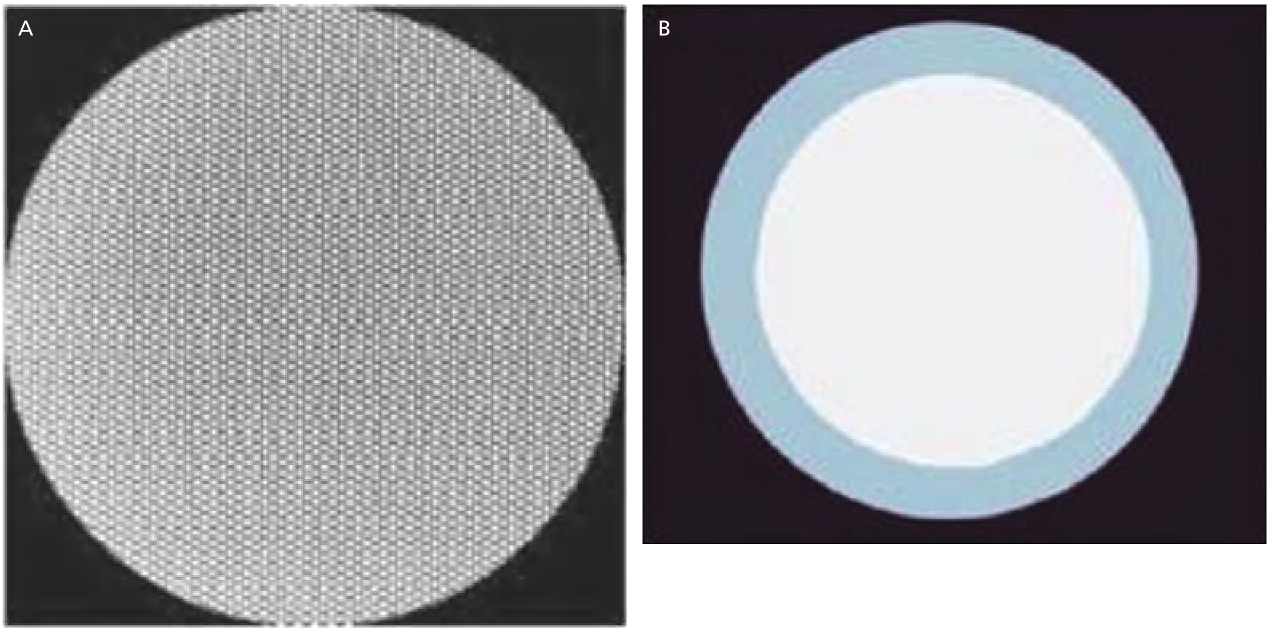

Figure 34.6 (A) Magnified view of composite images from a flexible fiberoptic imaging bundle and (B) magnified view of a single fiber with a central glass core and cladding of different optical refraction.

effect. Digital endoscopes are fundamentally different from their analog counterparts with no fiberoptic cable or viewing ocular lens. Instead, the image seen at the distal tip of the scope is electronically and digitally transferred through a single cable and recreated on a televisions monitor. The catalyst for their creation came from work in 1970 by Boyle and Smith who produced a microchip that could store electric charge (the CCD) for storage of data that could be retrieved at a later time [29]. A similar low-cost storage alternative was patented in 1967 and called the complementary metal oxide semiconductor (CMOS). Both CCD and CMOS devices are digital sensors composed of millions of photodiodes that convert photons into electric current that is transformed into a voltage, amplified, and converted to a digital form [30]. The image is digitally transferred via a single cable to a distant processor, which reconstructs and enhances the image electronically on a television monitor. These high-quality images, once captured, can be easily stored and transferred using a commercially available computer storage medium.

In 2005 the first commercially available distal sensor endoscope was the ACMI DCN-2010 digital cystoscope. With a digital camera and light emitting diode (LED) light carriers the net gain was better image quality and improved contrast, resolution, and color discrimination [31, 32]. Additional benefits included a lighter scope with less cabling and improved ergonomics. Such was the improvement with the digital sensor endoscope, lesions down to 1 mm in size could be clearly identified at a greater distance when compared with the fiberoptic scope. The introduction of the distal sensor endoscope represents an important historical landmark in the development of the endoscope.

Flexible ureterorenoscopes

Flexible fiberoptic ureterorenoscope

Given the complexity of engineering and construction of the flexible ureterorenoscope, it is surprising to find that its inception predated that of its semi-rigid counterpart by over a decade. In 1960 Marshall reported the first clinical use of a 9F fiberscope produced by ACMI to visualize an impacted ureteral stone during open surgery through a ureterotomy [33]. This ureterorenoscope was rudimentary in function with no active deflection. Marshall's colleagues, McGovern and Walzak, made the first transurethral flexible ureteroscopy 2 years later with the 9F fiberscope passed through a 26F McCarthy endoscope to a level of 10 cm in the ureter to diagnose a ureteral stone. In 1968, Takagi *et al*. similarly performed transurethral ureteroscopy using a small 8F passive, channel-less, fiberoptic endoscope of 70 cm in length to visualize the renal pelvis and calyces [34]. Manitol-induced forced diuresis was often required to make up for the lack of an irrigation channel. With increasing improvements in fiberoptic technology, Takagi *et al*. reported the first clinical use of an actively deflectable fiberoptic ureteroscope [35], which allowed some maneuverability of the tip of the scope. The fiberoptic ureteroscope was limited by the small

deflection angle and lack of an irrigation channel, and was difficult to insert. The subsequent development of a cystoscopically placed guide tube into the ureter (the original access sheath) allowed irrigant flow around the perimeter of the instrument for better visualization of the ureteral mucosa and pathology [36], though the views obtained were still far from ideal. The supportive nature of this technique did offer some protection when passing the delicate flexible scope, a problem that had hampered previous flexible scopes, which tended to buckle without the additional support.

The next evolutionary step in flexible ureteroscope design came in the 1980s when the inclusion of an irrigant and working channel were combined and incorporated into the next generation of ureteroscopes at the University of Chicago by Bagley *et al*. [37, 38]. For therapeutic and diagnostic purposes, such channels were essential. At the same time, a further technical advance was the development of ureteroscopes that could actively be steered, leading to endourologists being able to treat upper urinary tract pathology. Takagi's group had previously noted when passing the endoscope through a catheter that additional torque could be applied, allowing them to persuade the tip to pass in the desired direction, and thus establishing the importance of developing a deflectable tip endoscope. In 1983 a newly designed 55- and 80-cm flexible tip ureteropyeloscope was trialed by Bagley *et al*. [37, 38]. The tip deflection, which was in the same plane, was bidirectional: 160º in one direction and 90º in the opposite direction. Removing the telescope of the rigid ureteroscope allowed the flexible ureteroscope to be passed through the rigid sheath. To determine the optimal amount of tip deflection necessary to examine the entire intrarenal collecting system, Bagley and Rittenburg measured the angle between the major axis of the ureter and the lower pole infundibulum (the ureteroinfundibular angle) from the radiographs of 30 patients [39]. The average angle was 140º with a maximum of 175º. Primary active deflection of 175º should allow ureteroscopic negotiation of this ureteroinfundibular angle in most patients.

Several flexible deflectable ureteroscopes became available in the late 1980s, varying in size from 8.1F to 10F and with working channels of differing diameters. Despite the reduction in size due to advances in optical technology, access to the lower pole calyceal system remained difficult. In 1991 Grasso *et al*. reported the use of a small diameter, actively deflectable flexible ureteroscope [40]. This new scope had a tapered design with an 8.2F proximal sheath and a 7.5F distal tip giving improved access to the ureteric orifice. The working channel was maintained at a respectable 3.6F, allowing the use of most instruments. The instrument was capable of active deflection of 170º (down) and 120º (up) with secondary passive deflection if required, both of which gave successful appraisal of the intrarenal collecting system, in particular the lower pole. The addition of passive deflection allows lengthening of the deflected segment and permits inspection and treatment of the entire intrarenal collecting system [41, 42]. Secondary passive deflection is made possible by the presence of a more flexible segment of the ureteroscope located just proximal to the point of active deflection (Figure 34.7A); this allows the angled tip of the ureteroscope to be bent off the superior margin of the renal pelvis, or the neck of a middle-pole calyx when a baggy extrarenal pelvis is present. This effectively extends the tip of the ureteroscope, allowing inspection of the lower pole calyces with greater ease. This portion of the collecting system can be visualized in over 90% of patients when passive deflection is possible [41]. The latest advances in active deflection incorporate secondary active deflection into a flexible ureterorenoscope design. The first such scope was the DUR-8 from ACMI. This unique arrangement allows the operator to deflect the scope tip upwards by 175º and downwards by 185º by fully activating the primary deflection lever on the handpiece, and then by activating a second lever on the opposite side of the handle, a further 135º downward deflection of the tip can be obtained, to give a total of 315º downward deflection. The primary purpose of such a design is to access the lower pole calyces, which are usually the hardest to reach (Figure 34.7B, C).

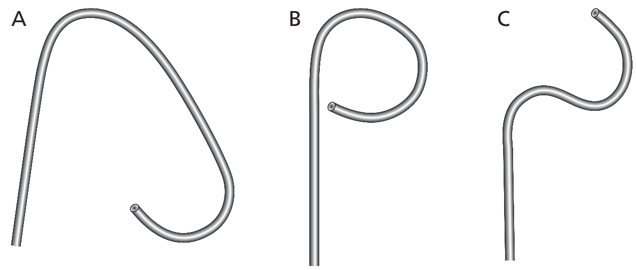

Figure 34.7 (A) Demonstration of a flexible ureterorenoscope's primary active deflection followed by a secondary passive deflection. (B, C) Dur-8 Elite flexible ureterorenoscope, the first instrument to incorporate secondary active deflection (courtesy of Olympus Medical).

Flexible digital ureterorenoscope

The impact of the arrival of the digital sensor ureterorenoscope should not be underestimated and the emergence of this new technology has great potential. Following on from the introduction of the ACMI DCN-2010 digital flexible cystoscope in 2005, the following year saw the launch of the ACMI DUR-D digital flexible ureteoscope (Figure 34.8; see Table 34.4). The scope utilizes the CMOS distal imaging sensor measuring 1 mm and built-in LEDs for illumination, negating the require-

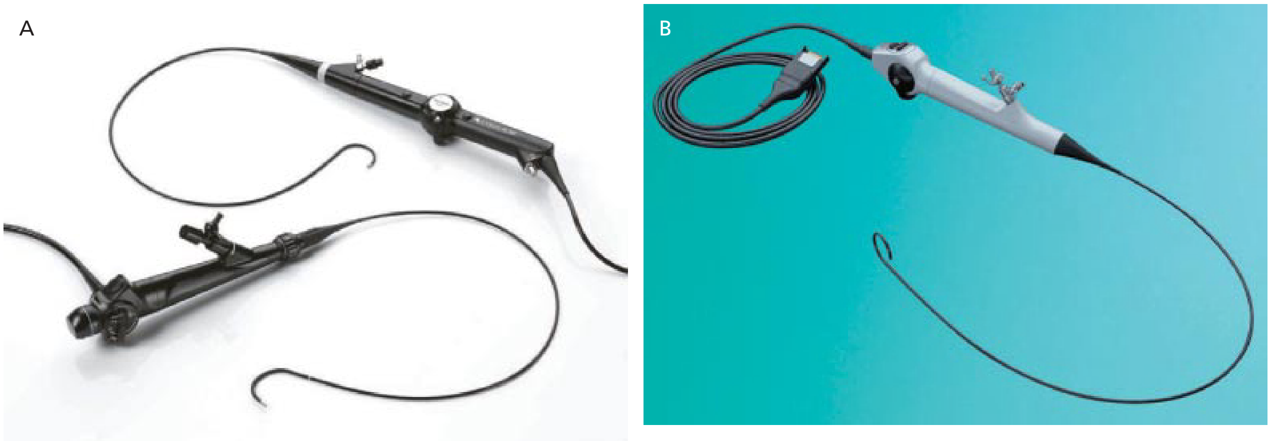

Figure 34.8 (A) Olympus DUR-D and ACMI DUR-D, and (B) Storz Flex-XC video ureterorenoscopes (courtesy of Olympus Medical and Karl Storz, respectively).

ment for a separate bulky light source. During its initial use, some concern was highlighted regarding the use of lasers down the working channel, which led to interference with the CMOS chip and a poor image. Through software upgrade and fine-tuning of the electronic circuitry, this problem appears to have been overcome. The shaft is constructed of nitinol for strength, lightness, and durability, and is tapered in design.

General properties

Flexible fiberoptic ureterorenoscope

Traditionally, all flexible endoscopes have involved similar basic components, including a fiberoptic bundle providing imaging and a light source, a working and irrigation channel, and a deflection mechanism. In addition, but of no less importance, are the camera, video system, and pressurized irrigation supply. Although the earlier generation of flexible fiberoptic ureteroscopes was limited by the lack of irrigation, active deflection, and instrumentation, with continuous refinement and improvement in all these areas the modern flexible ureterorenoscope now has a narrower shaft diameter with increased active tip deflection facilitating passage of scopes into the upper ureter and lower pole calyx [43]. The design of newer endoscopic instruments and energy sources has led to further advances in and miniaturization of endoscopic construction. The following sections discuss general details specific to the fiberoptic ureteroscope before moving on to state-of-the-art distal digital sensor ureteroscopes.

Conventional imaging

Along the full length of the shaft, each ureterorenoscope has one or two haphazardly arranged noncoherent bundles for light transmission, plus a single coherent fiberoptic bundle for image transmission. Using two sets of light transmission bundles gives consistent illumination and decreased shadowing. The fibers found in the bundle carrying the image are smaller and are aligned end-to-end in an identical arrangement so that the exact image is transmitted to the ocular lens at the eyepiece. The image obtained is not a single image but is formed by the addition of every individual fiber within the bundle to give a single reconstructed image (see Figure 34.6). Each optical fiber in the bundle is approximately $8\,\mu m$ in diameter and is composed of glass possessing a higher refractive index than the surrounding cladding. This composition allows for excellent light and image preservation over long distances and around significant flexion of the bundle.

The angle of view from the tip of the instrument can be modified by changing the axis of the optical system at the tip [44]. This is usually accomplished with a wedge lens system at the distal end of the imaging bundle. This modified angle of view can be up to 10° in fluid and is helpful in visualizing working instruments as they emerge from the tip of the scope. This is particularly helpful when using the more translucent laser fibers, which, being made of quartz, can easily cause inadvertent damage to the urothelium if not carefully directed away. The field of view (depth of image) is limited compared with the rod–lens optical system of the rigid endoscope; thus flexible ureteroscopes are equipped with focusing mechanisms and image magnification to compensate for that loss. The ocular lens at the eyepiece produces a virtual image. The distance between the virtual image and the operator's eye is adjusted by the focusing control. Changing this distance compensates for any visual acuity differences between operators and allows for variation in the depth of field. The effect of image magnification depends on the

distance from the object being viewed to the tip of the scope, with greater magnification produced the closer the object is to the distal tip [28].

Sheath dimensions

The working length of the newer flexible ureterorenoscopes ranges from 54 to 70 cm. The initial diameter of the flexible ureteroscope was significantly larger than the rigid scope and this necessitated that the ureter required ureteral dilation before its insertion. With time, the flexible ureteroscope has been streamlined and produced with a tapered shaft, allowing easier, less traumatic insertion. The tapering of the shaft usually leads to a flat, flush surface, though some scopes incorporate a beveled triangular design. Currently, the proximal shaft diameter can vary between 5.8F and 11F, and the tip diameter from 4.9F to 11F. Work by Hudson *et al*. showed that flexible scopes with a diameter less than 7.5F had a failure rate of approximately 1% compared with 15% for scopes with a diameter greater than 8.5F [45]. The use of a smaller diameter ureteroscope has also been associated with a reduction in ureteric complications.

Deflection mechanism

Active deflection of the tip of the ureteroscope is of fundamental importance to the success of diagnostic and therapeutic ureteroscopy [46]. Deflection of the thumb lever located on the hand-held portion of the ureteroscope places tension on control wires that run from here through movable metal rings within the shaft of the scope to the distal tip where the wires are fixed. The wires are effectively shortened by moving the control lever in order to get a range of deflection, which varies between scope models from different manufacturers. This results in tip deflection in the direction of that wire. Deflection in the opposite direction is accomplished by a wire on the opposite side of the ureteroscope. Control of the deflection lever is said to be "intuitive" when the tip moves in the same direction as the lever (an upward deflection on the handle lever deflects the scope upwards, and *vice versa*), or it can be "counterintuitive" (an upward deflection on the handle deflects the scope tip downward). Improvements in primary active deflection mechanisms now allow controlled deflection of the tip by up to 180º or greater, either up or down in the same plane.

Almost all current flexible ureterorenoscopes in addition to primary active tip deflection have secondary passive deflection where a proximal segment of the flexible ureteroscope shaft can become passively deflected on contact with the tissue (see Figure 34.7A). The passive segment is located just proximal to the point of active deflection, and is more flexible than any other part of the scope. The addition of secondary passive deflection allows lengthening of the deflected segment by moving the point of deflection more proximally, which effectively lengthens the tip of the shaft, permitting inspection and treatment of the entire intrarenal collecting system [23]. The main advantage of this design feature is to allow advancement of the tip of the ureteroscope into the lower infundibulum, allowing inspection of the lower pole calyces. Current flexible fiberoptic ureteroscopes all have enhanced active tip dual deflection in either direction with increased downward and upward deflection up to 270º (Figure 34.9). The maximal deflection is achieved using a single lever, which produces a broader radius of deflection, facilitating entry into the lower pole infundibulum. The ACMI DUR-8 Elite is unique in that it has two segments of active deflection to generate an enhanced tip deflection, which are operated by two levers found on the opposite sides of the ureteroscope handle (see Figure 34.7A).

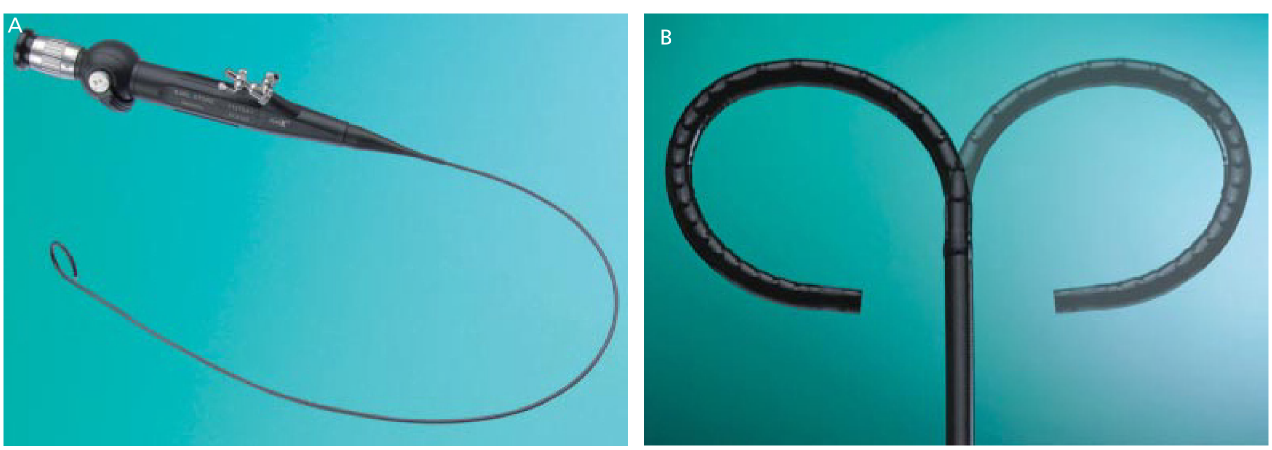

Figure 34.9 Karl Storz Flex-X2 ureterorenoscope with enhanced active tip deflection of 270º in both directions (courtesy of Karl Storz).

Figure 34.10 Tip design of the Flex-X2 ureteroscope demonstrating the ends of the optical system, light transmission bundle, and working channel (courtesy of Karl Storz).

Working and irrigation channels

The working channel was incorporated into the flexible ureteroscope in the 1980s, giving these scopes the ability to irrigate the field of view and pass instruments under direct vision, including laser fibers, electrohydraulic lithotripsy probes, biopsy forceps, stone baskets, and stone graspers, depending on the size and design of the working channel (Figure 34.10). The majority of the available flexible ureterorenoscopes have a 3.6F working channel, which allows the use of most accessory instruments that range in size from 3.2F to 1.5F. Larger 4.5F channels do currently exist and are specifically designed to accommodate a pneumatic contact lithotripsy flexible probe. However, with lasers fibers of diameters ranging from 150to 400 µm becoming increasingly used for contact lithotripsy, tissue destruction, incision, and fulguration, the requirement for ureteroscopes with working channels greater than 3.6F is questionable.

The working channel is formed from a smooth cylindrical plastic tube that travels the length of the shaft from the lower part of the handle to the tip of the scope, and is usually located eccentrically or offset at the tip. This eccentricity is less accentuated in the smaller-diameter ureteroscopes, because such a design causes less distortion of the working channel when the tip is deflected and allows for easier passage of working instruments [24]. Also, rotation of the ureteroscope may not be necessary when passing it through the ureteral orifice. The introduction of an endoscopic instrument into the working channel lumen invariably reduces active tip deflection and irrigant flow. For the newer small diameter flexible ureteroscopes, Chui *et al*. noted that deflection was less affected, though at the price of reduced rate of irrigant flow compared to older generation scopes [47]. The composition of the working instrument also appears to influence tip deflection, with stiffer accessories such as graspers and baskets composed of steel and polyamide resulting in reduced deflection capacity of the scope tip as compared to accessories made of either Teflon or nitinol. In a further study by Perry *et al*. [48], it was shown that the deployment of a 200-µm laser fiber in the working channel of a DUR-8 ureteroscope reduced primary deflection from 143° to 115°, while a 500-µm laser fiber reduced it further to 47°, but a nitinol accessory reduced it only to 123°.

Table 34.5 Irrigation flow rates for 3.6F working channels.

	Gravity (mL/min)	60 mL syringe (mL/min)	Roller pump (200 mmHg) (mL/min)
Empty channel	32–35	110	104
2.5F instrument	5–7	24–55	26
0.038-inch wire	2	21	N/A

In addition to reducing active tip deflection, the introduction of an instrument through the working channel will decrease the available lumen for passage of standard irrigation [49]. The use of smaller working instruments has again lessened the effect on flow reduction, and the use of higher-pressure irrigation as delivered by a pressurized irrigation bag, roller pump, hand-held syringe or bulb device (Bulbmaster), or foot-controlled device (Peditrol) can adequately compensate (Table 34.5). Flow rates of the order of 20 mL/min provide adequate visualization in most circumstances, though the downside of pressure irrigation is the increased risk of septic systemic complications from pyelorenal reflux, and the possibility of seeding tumur cells if present [50].

Column strength and tip deflection

The first flexible ureterorenoscopes had poor column strength and would buckle very easily [46]. As a consequence, the scope had to be passed through an access sheath or stiffened temporarily by placing a 0.035- to 0.038-inch wire either antegrade or by back-loading the rear end of the wire onto the tip of the scope. The latter technique had the potential to shorten the life of the ureteroscope and often required the active involvement of a primary surgeon and an assistant to facilitate passage of the instrument. The newer generation of flexible ureterorenoscopes has addressed this design issue and increased column strength, using improved proprietary polymers to give greater crush resistance as well as torque stability (Flex-X, Storz), while others have used a nitinol shaft design with a super slippery outer coating (DUR8-Elite, ACMI). The net result is a stiffer but torque-stable durable shaft, in essence producing almost a semi-rigid instrument but with a flexible deflectable tip.

Bends in the shafts of flexible ureterorenoscopes may severely restrict subsequent active tip deflection by as much as 61º [46]. In a study of scopes from all major manufacturers by Monga and Durfee, bending pressure was defined as the force required to deflect the tip of the ureterorenoscope by 15º from a baseline horizontal position [51]. These authors found bending pressure to vary from 6 g for the Wolf 7325.172 ureterorenoscope (7.5F), to 10 g for the ACMI DUR-8, to 12 g for the 9F Wolf 7330.072 instrument. Holding the instrument taut, placing a super-stiff guidewire in the shaft portion of the working channel, thus effectively stiffening it, or using an access sheath maximizes active deflection of the instrument tip. The insertion of a wire however, has to be balanced against the inevitable reduction in flow and vision, as well as hindering the possibility of injecting contrast down the working channel. The strength of the tip deflection, arbitrarily defined as the force that results in a loss of 10º active deflection, varies intrinsically from scope to scope [51] across a range from 46 to 265 g. As mentioned above, this figure can be limited by the additional rigidity of instruments within the working channel [34].

Light source

Light transmission to the tip of the scope begins with the source lamp. The most commonly used high-intensity light sources are halogen (150 W) and xenon (300 W)[28]. Such light sources have an automatic light-sensing feature, which can adjust the amount of light to the preset requirement of the camera. This function is particularly helpful during endoscopic procedures where different levels of illumination are encountered throughout the procedure. Alternatively, some digital cameras contain a light-sensing feature or automatic iris, which electronically increases or decreases the aperture of the camera shutter. With these cameras, there is no need for an automatic intensity-adjusting light source.

A flexible light cord, which is also made up of fiberoptic bundles, transmits the light to the ureteroscope. The light cord can either plug onto a post on the ureteroscope (a separate cord) or be incorporated into the ureteroscope (an integrated cord). The fiber bundles of an integrated light cord are continuous with the light bundle fibers travelling through the scope. A separate light cord will connect to a post on the scope to transmit light to the light fiber bundles. This connection invariably produces some loss of light power because of the inability to get perfect alignment of the fibers of the cord with those of the ureteroscope itself. This is usually not a significant problem because much more light is transmitted via the cord than is actually needed. The advantage of having a separate light cord is that only the cord must be replaced if it is damaged. One manufacturer of scopes (ACMI), using the separate cord arrangement, has patented a rotatable light cord connection post so that it can be rotated into a convenient place for the operator, whilst accessing the working channel.

Camera and video systems

The image seen from the ureteroscope can be either visualized directly by the operator's eye or by a range of cameras and monitors. Furthermore, the camera can be either fixed or free to rotate, with the image presented on the monitor orientated by the camera and not the endoscope. The top of the image on the monitor is therefore related to the top of the chip within the camera or in the ureteroscope. During cystoscopy, the image viewed at the eyepiece is readily orientated relative to the bladder and viewer. As the cystoscope is rotated, the trigone remains posterior and the dome of the bladder is at the top of the image. This same orientation is maintained with a rotating camera, which stays in one position relative to the patient. If the camera is fixed so it does not rotate but moves with the rotation of the cystoscope, as the cystoscope rotates 90º, the lateral wall of the bladder will appear at the top of the screen with the opposite wall at the bottom of the screen. This orientation occurs with the video chip cameras, which are fixed relative to the endoscope rather than the patient.

Traditionally, analog images have been transmitted through the fiberoptic bundles and converted into continuous waveforms before being displayed on an analog video monitor. Digital technology has revolutionized this process, as the digital image is not as susceptible to the degradation witnessed with the analog format. The digital format is ideal for taking digital still images and video, and this is an ideal format for storage. Current digital cameras capture the image on a CCD or CMOS chip. Each digital image is composed of millions of tiny dots of information or pixels. Each pixel corresponds to a charge generated by the CCD proportional to the light striking it. The pixels are then transferred to a storage element on the chip. The number of pixels and the number of CCD chips determines the resolution of the camera. The later cameras contain a prism-based-3 chip (multisensory) system, with a separate chip for each primary color (red, green, blue, RGB) giving a high-resolution output. The information from the three CCD sensors is processed and is amenable to modification by image processing software within the camera. The digital information is then transmitted to the television monitor to form a complete image. The original single-chip camera is less expensive and lighter, though it has poorer resolution.

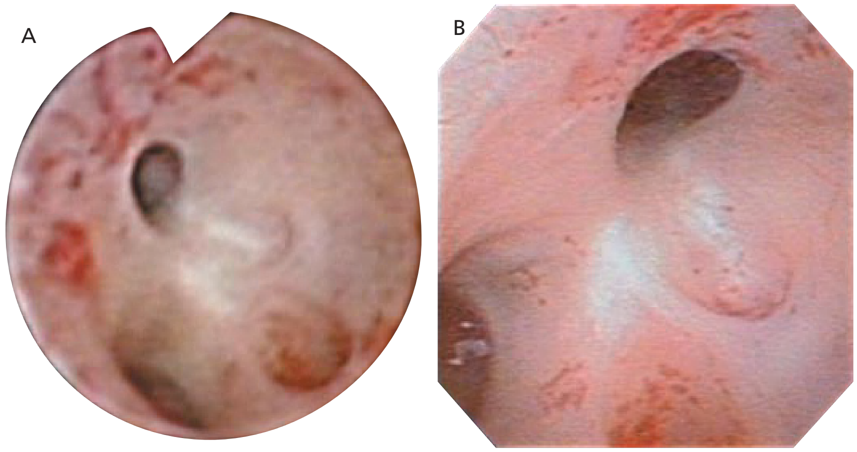

Figure 34.11 Comparison of image from fiberoptic ureterorenoscope versus Olympus URF-V Distal digital ureterorenoscope (courtesy of Olympus Medical).

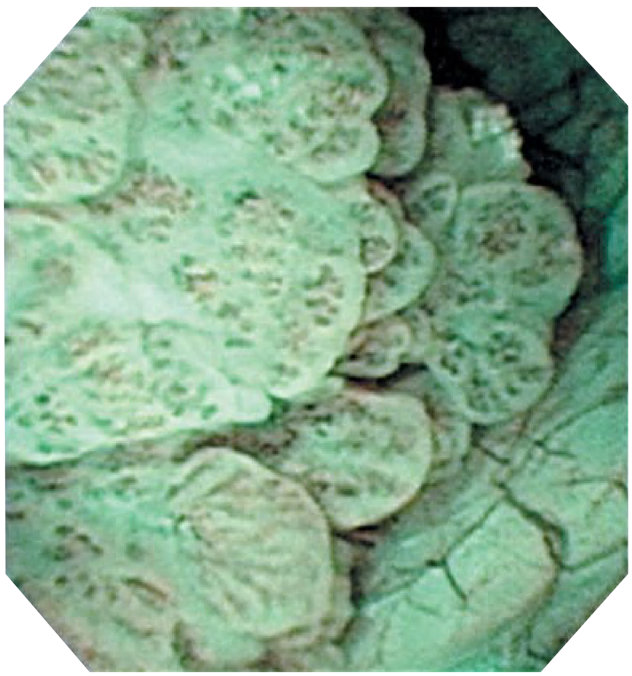

Figure 34.12 Narrow-band imaging as seen through the Olympus URF-V (courtesy of Olympus Medical).

Digital video ureterorenoscope ("chip on a stick")

Conventionally, optical images have been relayed from the objective lens at the distal end of the endoscope to a direct viewing lens and camera attached at the eyepiece. Instead of the rod–lens design or fiberoptic cables, a CCD sensor at the distal tip of the endoscope allows digitized information to be relayed back via a single fiber to a distant processor that reconstructs and digitally enhances the image electronically on a television monitor. The image quality is equivalent to ten times the pixel resolution of standard fiberoptic endoscopes (Figure 34.11). A further advantage of digital imaging is the ability to magnify an image up to 1.35 times. This technology has coincided with the arrival of high-definition digital television (DDV) to show the images to their full potential. It is envisaged in the future that further benefits will be gained as a result of losing the bundled fiberoptic cables, including smaller sized scopes, larger working elements, increased flexibility, and improved scope durability. The latest generation of digital ureteroscopes has already shown enhanced diagnostic capability with greater resolution of small mucosal lesions that could be missed with fiberoptic scopes.

Another function made possible by the use of a digitalization of the ureteroscope is narrow-band imaging (NBI) which is a feature specific to Olympus endoscopes. NBI is enabled with filters that restrict the wavelengths of light used for imaging to a narrow segment of the spectrum used in conventional white light endoscopy. To change from conventional white light endoscopy, the operator simply presses a switch on the endoscope to activate the optical filters. NBI is thought to enhance the appearance of both the epithelial surface and high-density microvessels associated with neoplasia (Figure 34.12). It is hoped that the sensitivity of detection of upper tract transitional cell carcinoma (TCC) may be improved using this technique, leading to earlier diagnosis, reduced recurrences, and long-term survival. Further clinical assessment is currently awaited.

Current ureteroscopes

The specifications of currently available flexible fiberoptic and distal sensor ureterorenoscopes are summarized in Table 34.6. Knudsen *et al.* performed a prospective multiinstitutional clinical trial randomizing patients to one of four available fourth-generation flexible ureteroscopes: the Wolf Viper, Olympus URF-P5, Gyrus-ACMI DUR-8 Elite, and Stryker Flex Vision U-500 [52]. The

*Distal sensor digital ureteroscopes.

ACMI DUR-8 Elite and the Stryker Flex Vision are unique in offering an active primary and secondary deflection mechanism activated by a dual lever mechanism found on the ureteroscope handle. The Dur-8 Elite has a maximum unidirectional down deflection of 315° when both levers are activated (see Figure 34.7A). It must be noted that if the point in the shaft where secondary active deflection is controlled is too far proximal from the tip, it may be fixed in the upper ureter at or below the UPJ, and this may negate any possibility to gain extra primary or secondary active deflection. The Flex Vision U-500 has bidirectional deflection of greater than 270°. Of the other two ureteroscopes examined, the Olympus URF-P5 has an upward deflection of 180° and a downward deflection of 270°, whereas the Wolf Viper offers active deflection of 270° in both directions. The Flex X2, which was not included in the study, has bidirectional primary deflection of 270° (see Figure 34.9). Although the Olympus, Wolf, and Stryker scopes showed similar durability, the group found that the Wolf Viper had better visibility and maneuverability ratings when compared with the other scopes. This finding is consistent with previous studies and is thought to be due to the Wolf's unique fused quartz bundle optics.

Given the potential advantages of the digital ureteroscopes, it is hard to envisage that the fiberoptic instruments will remain in circulation beyond the next decade. The two flexible video ureterorenoscopes currently commercially available are the Olympus URF-V, which utilizes a CCD chip and has the optional NBI function, and the ACMI DUR-D which incorporates CMOS chip technology (Table 34.6). Karl Storz has introduced the Flex X^C video-ureterorenoscope, which has the CMOS chip at the tip along with the Laserite thermal damage protection technology employed in the previous generation of Storz flexible ureteroscopes (Table 34.6).

Multescu *et al*. compared the Olympus URF-V digital flexible ureteroscopes with the Storz 11274AA flexible fiberoptic scope [53]. The group compared maneuverability, visibility, inferior calyx approach, maximal tip deflection and irrigation flow, and endoscopes fragility. The distal sensor ureteroscope scored higher on maneuverability and visibility, and had minimal loss of tip deflection on instrumentation when compared with the fiberoptic scope. Furthermore, superior rates of irrigation flow were seen for the digital flexible scope both with and without instruments placed down the working channel. The only downside to the Olympus URF-V was the larger distal tip of the scope that may reduce its accessibility to narrow segments of the collecting system.

Flexible ureterorenoscope technical failure

The flexible ureterorenoscope by nature of its function requires more working parts than the semi-rigid scope. Over the years this has led to issues regarding their reliability and concerns over the regularity of costly repairs that can often be time-consuming. Although reliability has improved following a greater understanding of the mechanisms leading to scope failure [54], the ureteroscope of the future needs to be increasingly robust to meet the rigors of frequent daily use and to prevent costs from escalating. Factors that have been considered to be significant in technical failure of the ureteroscope have included: features inherent to the design of the flexible ureteroscope, complexity of the endourology procedure, experience of the surgeon and personnel assisting the case, the techniques adopted for the procedure [55], and the sterilization process [56].

The introduction of lasers for contact lithotripsy, tissue destruction, incision, and fulguration has significantly increased the usefulness of the flexible ureteroscope, and a study by Pietrow *et al*. has shown that this has increased the longevity of the flexible ureteroscope [57]. The use of the laser can, however, potentially shorten the ureteroscopes working life due to damage of the working channel from use of the laser fiber when the tip is located close to the end of the ureteroscope or from laser malfunction. The main risk of *in situ* fragmentation of stones with a maximally deflected scope tip is unseen damage to the inside of the working channel at the point of maximum deflection, owing to energy released from microfractures of the stiff quartz core material. In most instances, this damage will not be discovered until after the scope has been sent for sterilization prior to next use, but may be suspected if there is no visible response of the target to energy discharge after foot–pedal activation. In general, it is better to relocate the stone into a more favorable position (upper or middle calyx) within the kidney or into the ureter (for smaller stones) before it is treated, if the life of the flexible ureterorenoscope is to be maximized. The practice of back-loading the ureteroscope onto the stiff rear end of the working wire can also lead to a hole being punctured in the working channel lining, raising an invisible internal flap that may prevent the subsequent passage of any additional accessories during the rest of the case.

The active deflection unit is the most fragile part of the flexible ureteroscope, with studies showing that deterioration in active deflection up to 28% can occur in instruments smaller than 9F in consecutive use [58]. Degradation in this unit or rough handling of the shaft can then lead to knock-on effects on the fiberoptic bundles. Even though the optical fibers are flexible, they are also quite delicate and may be damaged by excessive force or pressure on the shaft of the scope. An excessive force on the ureteroscope can develop when an extreme deflection force is attempted by the operator or alternatively when the turning circle of the deflectable tip is greater than the size of the renal pelvis, which is not

sufficiently capacious to accommodate the instrument. A prolonged approach to the lower pole calyx can also lead to a loss in deflection.

The estimated number of procedures that can be undertaken before the flexible ureteroscope requires a major repair has improved over the years from around 15 (or 13 h of usage) to approximately 50 [58, 59]. The need for repair occurs less frequently with the newer generation endoscopes and when the surgeon is more experienced. In the latest offering of flexible ureterorenoscopes from Storz, the Flex-X2, the working channel has a 1.5-cm ceramic-coated distal tip. This aims to protect the channel from damage when the laser is placed close to the tip of the scope. This instrument also incorporates a shock absorbing mechanism at the scope's deflecting segment. The durability of the current generation of scopes with exaggerated active deflection from other major companies (Olympus URF-P5, Gyrus ACMI DUR-8 Elite, and Stryker Flex Vision U-500) was recently assessed by Monga *et al*. [52]. The study aimed to see whether technologic progression in ureteroscope design translated to an improvement in durability. It was concluded that the DUR-8 Elite faired well in the clinical trials, yet this was at the expense of a major repair being necessary after the fewest average number of cases. The emergence of the digital flexible ureterorenoscope has offered the possibility of improved durability. Multescu *et al*. recently compared the current Storz fiberoptic ureteroscope with the Olympus URF-Vo digital endoscope and found that the digital set-up appears more robust with no loss of deflection encountered after 22 procedures [53].

Care, maintenance, and sterilization

Care of the small-diameter flexible ureteroscope begins with careful handling. In transit, the endoscope should be coiled loosely and not be bent as the glass optical fibers can easily be damaged. On handling, the scope should be held by the handpiece with the tip in a dependent position. Prior to insertion, the instrument should also be examined to ensure that all deflecting cables operate properly and that the tip can be deflected to the recommended extent in each direction. The operator should also check for optic fiber damage before and after each use, with broken fibers appearing as small black dots within the image. When over 20% of the fibers are broken, the ureteroscope should be sent for repair, as adequate light can no longer be transmitted. A light meter is needed for exact measurement. The optical fibers that transmit the image should also be checked both before and after each use. This is done by holding the scope tip close to the target object. If the image appears cloudy, the endoscope may need repair owing to moisture leaking into the optical fibers, which often occurs as a result of a breach of the working channel by a stiff guidewire or fractured quartz laser fiber. This ritual should again be repeated at the end of the operation.

During the case, the durability of the flexible endoscope can be improved by taking preventative measures to eliminate inadvertent damage from a laser fiber and by avoiding over deflection. With the use of instruments, iatrogenic scope injury can be avoided by straightening the tip before advancing the accessory through it, and the liberal use of jelly or silicone lubricant (e.g. Glide) to reduce frictional forces, though the working channels is some of the most recent models (e.g. DUR-8) have a slippery lining (e.g. DUR-8). Other methods for improving the longevity of the flexible ureterorenoscope have included routine use of ureteral access sheaths, nitinol devices, and 200-µm holmium fibers [57]. Having finished with the scope, further care must be taken in the sterilization of these delicate instruments. Ureteroscopes should be cleansed with warm water and a nonabrasive detergent to remove any debris following use (see Chapter 1). The working channel should be washed with a flow of water. This initial cleansing may be the most important step in the care and sterilization process [60]. Flexible endoscopes can then be sterilized by gas (ethylene oxide) or disinfected by soaking in a glutaraldehyde solution [60, 61]. Another option is the Steris system (Mentor, OH, USA). This system provides automated washing and rinsing of the endoscopes with a peracetic acid solution, which will sterilize immersible instruments in 30 min.

The control bodies and light guide connectors of modern endoscopes are constructed with a water-impermeable seal to protect the optical systems and working mechanisms from fluid or moisture seeping damage, and should be leak-tested before and after every procedure. During gas sterilization, changes in the temperature surrounding the endoscope can cause significant pressure changes within the sealed portion of the scope. A venting system, such as a valve on the light post, is important to equalize pressures during gas sterilization and prevent damage to the scope. Alternatively, some scopes have a more solid core with no internal air spaces, which then do not require an internal venting system.

Composite ureteroscopes

The cost-effectiveness of the flexible ureterorenoscope given the initial financial outlay and cost of repairs can be a significant burden to a urology department [62], especially in developing countries. The cost of carrying out 100 ureteroscopic procedures was estimated to

range from US$31 500 to $60 000 in a study performed by Landman *et al*. [63]. Sun Yinghao *et al*. envisaged that a hybrid ureteroscope with a rigid shaft combined with a deflectable tip might have a longer life-expectancy, which would benefit economically undeveloped countries in particular [64]. With technical help from Olympus, a rigid ureteroscope with the flexible tip of the Olympus URF-P3 flexible ureteroscope was fashioned. In total, 175 patients with renal calyceal calculi underwent deflectable tip rigid ureteroscopic lithotripsy with a holmium laser with a success rate of 83% stone clearance at 1 month. This new ureteroscopic technique was seen to have some definite advantages when compared with other types of traditional stone treatment. First, patients requiring ureteroscopy for stones in two different locations can have them treated with a single composite ureteroscope. Second, the tip of the ureteroscope can be controlled and orientated by manipulation of the rigid shaft. For some patients however, it was difficult to enter the renal calyces because of the short 60 mm length of the flexible ureteroscope tip. They concluded that ureteroscopic lithotripsy using the novel hybrid design is a safe procedure and combines the advantages of rigid and flexible ureteroscopy, especially for renal calculi of relatively small size.

Disposable ureteroscopes

Technical failure of the flexible ureterorenoscope most commonly occurs in the region of the active deflection unit and once damaged, the ureteroscope, if repairable, will require either a costly fix or even a replacement. It is therefore conceivable that an inexpensive, small caliber, disposable flexible instrument with similar deflection capabilities might decrease the initial outlay and overall investment. In 1987, Bagley reported the use of a flexible modular ureteropyeloscope in 38 patients [65]. The flexible tips of the ureteroscope were made available in 6F, 8.5F, and 11F, and all were replaceable. The instrument was successfully passed into the ureter in all but one patient, supporting the wider application of the equipment. Over two decades later, Boylu *et al*. published their findings comparing mechanical and optical properties and flow rate of the disposable flexible SemiFlex Scope (MariFlex, Baton Rouge, LA, USA) with six established, commercially available ureteroscopes [66]. The disposable ureteroscope consisted of a reusable eyepiece and semi-flexible shaft with a 3.5F working channel. The results showed that the disposable flexible ureteroscope had the highest active tip deflection, though the downside was that it had the greatest reduction in deflection with the introduction of a working instrument. The purchase price was, however, significantly lower and no further expenses were incurred. More recently, the Polyscope (PolyDiagnost, Pfaffenhofen, Germany), a steerable endoscopic catheter system with single-side active deflection, has been trialed [67]. In this early fit for purpose clinical evaluation, the Polyscope appeared easy to use, effective, and reliable, and may provide a financial answer to the inherent frailties of nondisposable scopes.

Future trends

The digital video endoscope is now here to stay and the endless possibilities using this technology are just starting to be realized. With further improvements in materials and endoscope design, the ability of the endourologist of tomorrow to diagnose and treat pathologic conditions affecting the urinary tract will continue to improve. It will not be long before all major endoscope manufacturers produce a distal sensor ureteroscope, and the endoscope of the future, whether rigid or flexible, will contain no viewing lens component. Further progress in digital technology will ensure further reductions in shaft diameter and the addition of increased functions, including wireless transmission of images to high-definition PC monitors, and potentially portable ureterorenoscopes. It remains to be seen whether these changes will result in improved durability. Robotic ureteroscopy is discussed in Chapter 48.

Three-dimensional ureteroscopy

Current endoscopic systems provide an image output in two dimensions with stereoscopic or three-dimensional (3D) imaging existing only in the domain of robotic and, rarely, laparoscopic surgery. With miniaturization of the CCD chips and future reduction in the cost of this technology, positioning two of them in the distal tip of the scope would enable stereoscopic images to be created with true depth perception. The advantages of 3D imaging during ureteroscopic procedures however, have not been confirmed and the additional costs may not be offset if the benefits prove to be small.

Virtual ureteroscopy

The use of virtual endoscopy for computer-driven reconstruction has been applied to multiple sites in the human body where there is a hollow viscus, including the renal collecting system and ureter [68, 69] (Figure 34.13). Although it is early days for this technology, this technique may prove to be useful as a noninvasive way of surveilling the urinary tract.

CHAPTER 35
Ureteroscopy Working Instruments

Renato N. Pedro[1] & Manoj Monga[2]

[1]AME-SBO Lithotripsy Center, State University of Campinas – UNICAMP, Santa Barbara D'Oeste, Brazil
[2]Glickman Urological & Kidney Institute, The Cleveland Clinic, Cleveland, OH, USA

Introduction

Before the birth of Endourology in the early 1980s, upper urinary tract diseases were managed through large open incisions, which were associated with significant associated patient morbidity [1]. The advent of flexible and semi-rigid ureteropyeloscopy has lead to less invasive treatment options for the upper collecting system. Over the course of time, lead by the interaction between engineering and medicine, the instrumentation and technique of endourology has continued to be refined and improved.

Patient preparation

After induction of anesthesia, the patient is placed in a lithotomy position with the ipsilateral leg slightly extended [2]. Though recommended primarily for patients with a moderate risk of thromboembolism [3], we routinely utilize pneumatic compression boots in all patients in the lithotomy position to decrease the risk of deep venous thrombosis and of intracompartment pressure [4].

The C-arm monitor, video monitor, and holmium laser machine are positioned on one side of the patient such that little movement by the surgeon is required to view the C-arm and endoscopic images, or operate the laser foot pedal. It is helpful to utilize software that draws the fluoroscopic image into a "picture-in-picture" format on the endoscopic image. Typically a flat-screen monitor mounted on a swivel-arm is utilized. The C-arm device is positioned on the other side of the patient to allow for free movement of the image intensifier from the kidney to the pelvis.

On occasion, if there is uncertainty as to whether the pathology may require a percutaneous approach, the patient may be positioned in a prone split-leg position, so that it is easy to proceed with posterior percutaneous renal access if needed [5].

Ureteral access

The use of a safety wire is encouraged for all urologic endoscopic procedures, though some authors suggest it is not needed if active stone basketing is not planned as part of the procedure [6]. Guidewires facilitate and maintain access to the upper urinary tract and may straighten an otherwise tortuous path. The ideal guidewire would require little force to bend in response to obstruction, and a large force to perforate through tissue. These properties were examined in an *in vitro* study of nine commercially available guidewires, and the lubricous, soft-tip nitinol glidewire (Boston Scientific, Natick, MA, USA) was the safest wire for initial access to the ureter, as it is less likely to perforate and more likely to bend at a point of obstruction [7].A standard guidewire would also have a fairly stiff mid-shaft to straighten the ureter and facilitate coaxial passage of other devices (sheaths, stents, etc.). It would have a floppy tip on the external end to facilitate atraumatic

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

back-loading of the flexible ureteroscope if needed. The Bard Sensor guidewire (Boston Scientific) is a hybrid wire that combines these components; a hydrophilic distal tip, shift shaft (nitinol core with polytetrafluoroethylene coating), and floppy proximal tip [8]. We typically utilize a 0.035-inch Sensor guidewire initially to cannulate the ureteral orifice and advance up to the level of the renal pelvis. If resistance is encountered, a 5F open-ended catheter is advanced to the level of resistance under fluoroscopic guidance and retrograde pyelography is performed to delineate the ureteral anatomy. A 0.035-inch straight-angle hydrophilic glidewire (Boston Scientific) is then placed through the open-ended catheter and advanced beyond the site of obstruction. For coaxial passage of ureteral access sheaths and large caliber stents and catheters, an Amplatz super-stiff guidewire kinking (Boston Scientific) is utilized to minimize the risk of wire buckling.

Torqueable catheters

At times the ability to guide a wire past a point of particular tortuosity may prove beneficial to establish secure guidewire access. One alternative would be to utilize an angled-tip guidewire and a torque device which attaches to the external end of the wire. Rotating the torque device reorients the tip of the wire to direct it towards the anticipated path of the lumen as outlined on retrograde pyelography. Alternatively, a variety of torqueable angled catheters (Kumpe, JB-1, Cobra) can be utilized to help guide the wire in the correct direction.

Ureteral access sheaths

Ureteral access sheaths facilitate expeditious and atraumatic entry and re-entry to the upper collecting system with the flexible ureteroscope, while eliminating the risk of buckling of the endoscope in the bladder. The use of a ureteral access sheath has been demonstrated to decrease operative time and cost, minimize patient morbidity, and optimize overall success of flexible ureteroscopy [9]. Specifically, a retrospective case series has demonstrated superior stone-free rates in a contemporary series of patients undergoing ureteroscopy with the use of an access sheath compared to no access sheath [10].

The access sheath also protects the upper urinary tract from increased peak intrarenal pressure, even with irrigant pressurized to 200 cmH_2O, as it allows efflux of irrigant through the sheath and around the ureteroscope, maintaining intrapelvic pressures below 20 cmH_2O [11].

Finally, some authors have suggested that the use of a ureteral access sheath decreases the risk of endoscope damage [12].

In vitro and randomized clinical studies have demonstrated that the Cook Flexor sheath (Cook Urological, Bloomington, IN, USA) is superior with regards to ease of placement, instrument passage, and stone extraction [13], is more resistant to both buckling at the ureteral orifice and kinking after removal of the inner dilator [14], and has one of the largest inner diameters in the most common positions of straight and 30° bends, which further facilitates stone extraction [15]. Recently, when compared to the next-generation of ureteral access sheaths, the Cook Flexor remained the most resistant to buckling, though the Gyrus-ACMI Uropass (Gyrus ACMI, Southborough, MA, USA) was more resistant to kinking [16].

A 12/14F ureteral access sheath is the standard size utilized for adults, as studies have demonstrated that this internal diameter optimizes irrigant flow and intrapelvic pressures [17]. Typically, a 35-cm length sheath is utilized for women and a 45-cm length sheath for men if the goal is to reach the ureteropelvic junction (UPJ). If the sheath does not go up the ureter, the inner dilator can be used without the outer sheath to dilate the ureter over a super-stiff guidewire. If unsuccessful, a ureteral balloon (see below) through the sheath may be used or a ureteral stent placed to passively dilate the ureter.

Intracorporeal lithotrites

While a number of different endoscopic lithotrites, such as ultrasonic, electrohydraulic (EHL), pneumatic, and laser have been utilized for ureteroscopic lithotripsy, the holmium laser has become established as the standard of care due to its efficiency, versatility, and safety. *In vitro* analyses have demonstrated that the holmium laser fragments all stone compositions and produces smaller stone fragments than pneumatic, EHL, and pulsed-dye (Candela) lithotripsy [18]. While EHL can cause damage even if fired several millimeters away, the holmium laser can be safely activated at a distance of 0.5–9 mm from the ureteral wall without risk of perforation as the energy is effectively absorbed in a fluid medium [19].

Holmium:YAG laser lithotripsy generates a photothermal process that leads to direct absorption of the laser energy by the stone and thermal combustion. It also creates a vaporization bubble that subsequently destabilizes and decomposes the stone [20]. In clinical trials the stone-free rates both at the end of the ureteroscopy and 3-months post procedure were significantly higher for the holmium laser than either EHL [21] or pneumatic lithotripsy [22].

Laser energy is brought to the target (stones) with the aid of laser fibers, which are thin and flexible, optimal characteristics for passing through the working channel of a flexible ureteroscope. Studies on performance and safety of commercially available holmium laser fibers demonstrated that the Dornier Lightguide 200 was the

most likely of the small fibers (200–273 mm) to fracture and damage a flexible ureteroscope, while the Lumenis 272 (Coherent, Santa Clara, CA, USA) and the Innova Quartz 400 (Gyrus-ACMI) were the most durable in their size class [23].

The 365-μm laser fiber is more durable and results in the best stone fragmentation efficiency [24]. However, the increase in size leads to a decrease in active deflection of the flexible ureteroscope; only 7–16% of maximum deflection (–9º to –19º) is lost with the 200-μm fiber compared to 18–37% (–24º to –45º) of maximum deflection with the 365-μm fiber [25, 26].

Pneumatic lithotripsy has the advantage, especially in areas where resources are limited, of low maintenance and disposable costs. The disadvantages of pneumatic lithotripsy are the increased risk of stone migration and the inability to apply this modality through a flexible ureteroscope.

EHL generates a spark which results in plasma expansion at supersonic speed, propagating a hydraulic shock wave and cavitation bubble. Collapse of the cavitation bubble leads to a second shock wave, which if asymmetric leads to the formation of a liquid jet. Each of these mechanisms results in stone fragmentation [27, 28]. However, the safety of the device is the primary concern, with one series reporting a 3% conversion rate to open surgery due to ureteral perforation in conjunction with a stone-free rate of only 58% at 3 months [29].

Ureteral occluding devices

A variety of devices have been developed to prevent stone migration during intracorporeal lithotripsy. The Stone Cone (Boston Scientific) consists of concentric coils which act to prevent proximal retropulsion of stone fragments, and it has proved to reduce the incidence of residual stone fragments greater than 3 mm in size [30]. The 2.8F Cook N-Trap (Cook Urological) is composed of 24 interwoven nitinol wires and in *ex vivo* pig ureters has been shown to prevent the migration of plastic beads as small as 1.5 mm [31]. Each device is designed to release any larger fragments as the device is withdrawn. It has been demonstrated that the Stone Cone releases the stone with a mean force of 0.19 lb and the N-trap with a mean force of 0.86 lb, suggesting a potential safety advantage with the Stone Cone [32]. More recently, the Percsys Accordion (Percutaneous Systems, Palo Alto, CA, USA) has been launched into market and proved in an *in vitro* comparative study to be as safe and efficient as the Cook and Boston Scientific counterparts [33].

In vitro studies have evaluated a biogel polymer that is delivered using a 3F ureteral catheter above the stone to occlude the more proximal ureter. The triblock polymer of polyethylene oxide is a liquid at low temperatures and turns into a gel at body temperature. Warm irrigation must be utilized during the procedure, then cold saline is instilled to liquefy the polymer at the completion of lithotripsy. Residual polymer dissolves in urine after 2 h and is expelled [34]. In a recent randomized clinical trial, Rane *et al*. reported the successful use of a water-soluble polymer (BackStop) to prevent stone migration during semi-rigid ureteroscopy. The study showed that this polymer was efficient in stabilizing the stone during laser or pneumatic lithotripsy; moreover, no adverse events were associated with its use compared to conventional ureterolithotripsy [35].

Each of these devices and techniques requires additional manipulation prior to ureteral lithotripsy, so the benefit of their use should be weighed against the additional risks of perforation in the face of a large ureteral stone. Specifically, their use may be most warranted in situations where pneumatic lithotripsy is planned and the risk of migration is higher, or if there is significant hydroureteronephrosis above the stone, or if there is limited availability of flexible ureteroscopy to retrieve stones that migrate.

Stone retrieval devices

A stone retrieval device is an essential instrument in ureteroscopy. Each device can be evaluated and distinguished by its ability to be visualized during stone manipulation, to provide radial force to open in the ureter, and to capture, retain, or, if necessary, disengage a stone. Alligator or rat tooth forceps are preferred by some due to their reversible grasp and reusability; however, their large size and weak grasp impact their effectiveness [36].

Nitinol-based baskets are more versatile due to the unique pliability of the wires and the flexibility that allows full lower pole deflection of a flexible ureteroscope in the majority of cases [37, 38]. *In vitro* studies have shown that the Cook NCircle 2.2F (Cook Urological) was the most efficient in capturing stone from a ureteral model, while the Sacred Heart Halo 1.5F (Sacred Heart Medical, Minnetonka, MN, USA) was the most efficient compared to 12 other baskets in a calyceal model [39–41]. If there are stone fragments adherent to the renal papilla, the Cook NCircle 2.2F basket wires are more pliable and can be distorted with gentle pressure until they embrace and grab the adherent stone fragments.

The Cook N-Compass (Cook Urological) with its webbed configuration is designed to optimize the retrieval of multiple small (1 mm or less) stone fragments that may result from lithotripsy of a large burden intrarenal stone.

The Bard Dimension basket (Boston Scientific) has a unique lever that extends two wires to “deflect” the cage of the basket. It has been proposed that this facilitates

retrieval of stones in hard to reach calyces and stone release if needed [42]. However other investigators have reported that this affords no advantage for either stone capture or release [43]. The Boston Scientific Graspit and Cook NGage are two devices that have coupled the properties of a three-prong grasper with the entrapment capability of a regular tipless nitinol basket. It has been proposed that they provide a better ability to grasp and release the stone [44].

The 1.5F Sacred Heart Halo has been demonstrated to be the most efficient at stone retrieval of smaller fragments and provides superior irrigation compared to the Microvasive Zerotip 1.9F (Microvasive Urology, Natick, MA, USA) [45]. In addition, it allows rotation of an engaged stone via a rotary wheel on the basket handle, and simultaneous laser lithotripsy, as a 200-μm laser fiber can be passed alongside the Halo basket; a technique that is utilized if a stone is too large for removal down the ureter. The 1.9F Escape nitinol stone retrieval basket (Boston Scientific) offers the same property of "side by side" approach, preventing retrograde ureteral stone migration [46]. These two devices are of particular interest in cases of entrapped ureteral or renal stones where laser lithotripsy prior to stone capture cannot be accomplished. Recently, the 1.3F Optiflex basket (Boston Scientific) has been released, and this is currently undergoing evaluation.

Ureteral balloon dilators

Ureteral balloon dilation is utilized in approximately 5% of cases, when the ureteral access sheath will not advance to the site of pathology due to ureteral stricture, spasm, or a tight ureteral orifice. Ideally, a ureteral balloon would dilate to 100% of the expected diameter regardless of any amount of radial constrictive force. An *in vitro* study compared the dynamics of ureteral balloon expansion under varying extrinsic compressive forces and inflation pressures [47], and concluded that at inflation burst pressure, the Cook Ascend AQ (Cook Urological) was the most reliable balloon, achieving and maintaining over 100% of the expected inflation diameter with minimal pressure and a small coefficient of variation. The Bard X-force balloon dilator, the only balloon rated to 30 atm inflation pressure, was not evaluated in this study.

Flexible ureteroscopes (see also Chapter 34)

Current flexible ureteroscopes offer increased lower pole access through exaggerated active deflection compared to older passively deflecting scopes. Some achieve this by incorporating separate dual-lever primary and secondary active deflection that offers increased unidirectional downward deflections of 270º (Gyrus-ACMI Dur8-E, Stryker Flexvision). Other endoscopes provide increased bidirectional primary deflection of up to 270º using one deflection lever (Gyrus-ACMI Dur-D, Olympus URF-P5, Karl Storz Flex-X2, Richard Wolf Viper). Recently, a dual-channel flexible ureteroscope, Wolf Cobra (Richard Wolf Endoscopy, Vernon Hills, IL, USA), has been developed that affords the opportunity to hold traction on soft tissue while transecting the tissue with a laser, or the ability to hold a stone in a basket while laser ablating through the second channel. This endoscope offers superior deflection and irrigation characteristics, in particular when larger 2.4F accessory instruments are utilized [48].

A comparative study of available flexible ureteroscopes showed that the Wolf Viper provides superior irrigant flow, and better visualization through the unique fused quartz bundle compared to glass fiberoptic bundles [49]. Moreover, the Wolf Viper 7.5F (Richard Wolf Endoscopy) was shown to have a twofold greater resolution than the other flexible fiberoptic ureteroscopes, and *in vitro* evaluations of scope manipulation have demonstrated that it is superior at accessing all calyces in a hydronephrotic kidney model [50].

Another critical consideration is the durability of the flexible ureteroscope. Afane *et al*. were the first to note that although the flexible ureteroscopes were highly efficient in diagnosing and treating upper tract abnormalities, after only 6–15 uses they needed to be repaired, mostly due to problems in the deflection unit [51]. Subsequently, a randomized prospective multicenter study demonstrated that the Gyrus-ACMI DUR-8-Elite was the most durable flexible ureteroscope circa 2005 [52]. The most recent randomized clinical study of the next generation of flexible ureteroscopes demonstrated that the Wolf Viper, Olympus URF-P5, and Stryker Flexvision U-500 flexible ureteroscopes appeared comparable with regard to durability, suggesting that some parity has been achieved between manufacturers [53].

Modern digital flexible ureteroscopes (Olympus URF-V, ACMI DUR-D) offer improved ease of handling and visibility as they have eliminated the light cord and improved optical resolution with complementary metal oxide semiconductor (CMOS) technology. Digital scopes employ the light emitting diode (LED) technology, a durable and cheap cool light, putting aside the traditional xenon light, an expensive and less durable heat-generating light source. The absence of optic fibers in the shaft of the flexible scope allows for better deflection and simplifies the instrument, which may lower costs, and improves maneuverability and durability [54]. However, Knudsen *et al*. recently reported that the distal lens of the digital ureteroscope appears to be extremely fragile and prone to breakdown, in contrast to what had been previously reported. The authors concluded that

to improve reliability and cost-effectiveness, refinements of the digital scope design are still required [55].

Disposable flexible ureteroscopes

A new cost-effective technology is available for retrograde access to the upper urinary tract, based on the premise of a single-use flexible endoscope, which eliminates the need for sterilization between cases. Basically, the disposable flexible ureteroscope comprises a reusable 10 000-pixel fiberoptic attached to a hand-held with a deflection lever, detachable light source, and irrigation source. For every new case a sterile 8F sheath is snuggly advanced over the fiberoptic shaft, keeping the later from touching the patient. This sterile sheath contains a 3F working channel and is capable of being deflected along with the fiber optic. Recently, it was reported by Boylu *et al*. that this new modality of endoscope has acceptable active tip deflection, field of view, and flow rate compared to six other flexible ureteroscopes on the market [56]; however, it is advised that this disposable ureteroscope is used for simple clinical cases, reserving the traditional reusable flexible ureteroscopes for more complex cases.

Endoirrigation systems

The passage of instruments through the working channel of a flexible ureteroscope can significantly decrease irrigant flow and result in poor visualization. Gravity with or without the assistance of pressure-bag compression is commonly utilized. With the use of a ureteral access sheath, intrarenal pressures can be maintained below 30 cmH_2O even with systems pressurized to 200 cmH_2O [57]. Alternatively hand-held, foot pedal, or automated irrigation systems may be utilized.

An automated irrigation/suction system (Endo-FMS Urology, Future Medical Systems USA, Glen Burnie, MD, USA) incorporates an irrigation roller pump with a suction roller pump (functional during rigid ureteroscopy only) to provide continuous flow and a controlled pressure. The Peditrol (EMS Medical Systems, Stroud, UK) is a foot pedal syringe-based irrigation system that functions by two separate one-way valves, one attached to gravity or a pressure bag and the other attached to a 3-mL syringe secured to the Peditrol foot pedal. The Boston Scientific single-action pump is a 10-mL vacuum syringe that has one-way valves that provide automatic refill of the syringe for immediate access to irrigation fluid.

Recently, an *in vitro* study evaluated the impact of stone migration with each system as well as the efficiency of irrigation to clear the operative field of blood, as measured by number of pulses and duration of irrigation. Of the hand-held devices, the single-action pump exerted the least impulse on a stone, decreasing the likelihood of dislocating the stone during the endoscopic surgery [58]. Though pressurized saline bags were not as efficient at clearing the operative field, they did result in less migration than hand-held or foot pedal devices.

Future innovations

Future innovations may lead to higher stone-free rates. Investigators are developing iron-oxide microparticles that bind to the calcium component of stones and provide the opportunity for expeditious extraction with a magnet-tip retrieval device [59].

Alternatively, future innovations may lead to a safer procedure. The addition of isoproteronol (a ß1,3-adrenoreceptor stimulant) to the irrigating solution during ureteroscopy relaxes the ureteral smooth muscle, leading to lower intrarenal pressures, which and may facilitate the passage of fragments, debris, or clot [60].

These are a few futuristic concepts that may lead to better outcomes for the patient and facilitate the procedure for the endourologist. Driven by innovation, endourology will remain a dynamic field, with evolving improvements towards the best clinical practice.

CHAPTER 36

Access to the Ureter: Rigid Ureteroscopy

Fernando C. Delvecchio
University of South Florida College of Medicine, James A. Haley Veterans Hospital, Tampa, FL, USA

Introduction

Technologic advances that allowed for downsizing of endoscopes, bigger working channels, improved working elements and video, and the advent of the holmium laser have revolutionized upper tract endoscopy and positioned it as a key diagnostic and therapeutic tool in the urologist's armamentarium.

Indications for distal ureteroscopy

The ureter is divided into proximal, mid, and distal segments. The proximal ureter extends from the ureteropelvic junction (UPJ) to the iliac crest. The mid-ureteral segment overlies the iliac wing. The distal ureter is defined as the segment distal to the pelvic brim and iliac vessels. Its intramural portion is fixed and narrow, and must be manipulated with care to avoid iatrogenic insults.

A semi-rigid endoscope usually grants easy access into the distal ureter and on occasions it can be used above the iliac vessels, especially in females or thin males without large psoas muscles. The semi-rigid ureteroscope can reach beyond the pelvic brim with some degree of bending, possible because it is constructed with fiberoptic bundles instead of the classic rod–lens system. However, the endoscopic surgeon needs to become familiar with the tactile feedback in order to avoid iatrogenic injury or scope damage.

Distal ureteroscopy is most commonly performed for the treatment of ureteral stones since ureteroscopic management of distal stones, regardless of stone size, yields better stone-free rates than shock-wave lithotripsy (SWL) [1]. Other indications include endoureterotomy for ureteral stricture, evaluation of filling defects on intravenous or retrograde pyelography, biopsy or ablation of upper tract transitional cell carcinoma (TCC), surveillance of previously treated TCC, and in combination with flexible ureteroscopy, for the evaluation of hematuria and/or positive cytology with normal cystoscopy.

Ureteroscopy is expanding its frontiers and now is becoming more widely accepted as first-line therapy after failed conservative management of urolithiasis in prepubertal children and pregnancy, urolithiasis in patients with urinary diversions, morbid obesity, and renal ectopia or fusion abnormalities [2–9].

Preoperative evaluation and patient positioning

Preoperative evaluation requires careful history taking pertinent to the urologic disease being treated, but also aimed at identifying pathology that may affect or compromise the smooth flow of surgery. Prior urologic procedures, pelvic radiation, or orthopedic conditions that may preclude adequate patient positioning need to be elicited.

An explanation of the procedure with its goals and potential complications, and the possibility of placing

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

an indwelling ureteral stent are discussed in the informed consent. The majority of ureteroscopies can be performed as outpatient procedures.

Of all preoperative laboratory studies, a negative urine culture is of paramount importance. It has been shown that for ureteroscopic lithotripsy with the holmium laser, bleeding diathesis does not need to be corrected; for all other ureteroscopic procedures, a normal coagulation profile is mandatory [10]. If the coagulopathy can be safely reverted, it is probably justified to do so since rigid ureteroscopic access may potentially require the use of balloon or ureteral dilators that even when used correctly can lead to trauma with ensuing bleeding.

The American Urological Association recommends 24-h antimicrobial prophylaxis for all upper tract instrumentation. Antimicrobials of choice are fluoroquinolones or trimethoprim–sulfamethoxazole (TMP–SMX). Alternative antibiotics include an aminoglycoside with or without ampicillin, a first- or second-generation cephalosporin or amoxicillin/clavulanate. In patients with renal insufficiency, aminoglycosides can be substituted for aztreonam [11].

After regional or general anesthesia, the patient is placed in the dorsal lithotomy or modified dorsal lithotomy position, depending on the surgeon's preference. In the modified position, the leg that is ipsilateral to the ureter being explored is lowered and slightly abducted as it is believed that this position aligns the affected ureter with the rigid instrument.

Video monitoring is routinely used because it is more ergonomic to the operating surgeon and facilitates the teaching of trainees. It also enables documentation either in the form of still pictures or movies that can be incorporated into the patient's electronic records.

Equipment for ureteroscopic access

Ideally, ureteroscopy takes place in a lead-shielded endourology-dedicated operating room, which consists of a fixed urology-specific endoscopy table with fluoroscopic capabilities and at least two monitors that receive fluoroscopic and endoscopic feed. The monitors, attached to ceiling mounted booms, are placed in front of the surgeon who stands in between the patient's legs. Fluoroscopy is controlled by the surgeon by activation of a foot pedal.

Operating room personnel must wear adequate protective gear, including lead aprons and thyroid shields. Dosimetry badges are needed to record individual exposure to radiation. Lead glasses are especially recommended for endoscopic surgeons due to their proximity to the radiation source and chronic exposure.

Basic equipment for all distal ureteroscopies includes a rigid or a flexible cystoscope, an open-ended ureteral catheter, guidewire(s), and contrast. Lenses of 12º and 70º, and a cystoscopic sheath greater than 17F to accommodate a ureteral catheter are needed if rigid cystoscopy is contemplated.

Guidewires

Guidewires are key to a successful endoscopic procedure because they allow constant access into the upper tract. Access is especially important during difficult cases because it enables the surgeon to negotiate a troublesome spot either to find back the ureter and continue with the ureteroscopy or to deploy a stent and return at a later date. Wires are also used to monorail ureteral dilators, sheaths, and flexible endoscopes into the upper tracts, and as such are made of different materials that enhance the purpose for which they were designed.

In general, guidewires have two components: an inner core that determines the stiffness of the guidewire shaft and the flexibility of the tip, and an outer coating that determines guidewire lubricity. Stainless steel core wires can be made to have different core stiffness (i.e. floppy tip vs super stiff) and can permanently kink if manipulated inappropriately. In contrast, the more expensive nitinol wires consist of a nitinol core with a polyurethane jacket and a hydrophilic polymer coating. Nitinol does not kink. The hydrophilic coating of the nitinol-type wires must be kept moist, because it becomes tacky if it dries out [12].

Polytetrafluoroethylene (PTFE)-coated, stainless steel wires with a floppy tip are probably the most common and least expensive wires. Hydrophilic (nitinol) wires with straight or angled tips absorb water to become very slippery and atraumatic, and are purposely designed to gain upper tract access in the setting of an obstructing stone or ureteral kink or obstruction. However, due to their slippery nature they are not suited to instruments being delivered over them and need to be exchanged once upper tract access is gained. Super-stiff wires are more kink resistant than the other types, and are therefore best used for proximal deployment of ureteral dilators (balloon, sheaths, or coaxial) and to "straighten"' a tortuous ureter. Hybrid or combination wires combine a flexible hydrophilic-coated floppy tip, which facilitates access, with a kink-resistant core that allows for working instruments to be delivered over them, thus avoiding the use of multiple other wires.

Ureteral dilators

Ureteral orifice dilation is seldom necessary when using the newer and smaller semirigid ureteroscopes. However, on occasions it is necessary to dilate the ure-

teral orifice or a more proximal ureteral stricture using either a balloon or a coaxial ureteral dilator or the obturator of an access sheath.

Balloon dilators have a deflated shaft diameter of 5F, balloon lengths between 4 and 10 cm, and an inflated profile of 12–30F. They are placed over a super-stiff or hybrid wire straddling the area of interest and inflated up to 20 atm of pressure with diluted contrast with a specially designed syringe. They produce radial dilation which is thought to result in less ureteral trauma than the shearing forces of ureteral dilators.

Polyethylene or PTFE coaxial dilators range in size from 6F to 18F and are sequentially passed over a wire under fluoroscopic vision across the narrow segment.

The ureteral access sheath is not used for semi-rigid ureteroscopy; however, if the surgeon anticipates a need for inspection of the more proximal ureter with a flexible ureteroscope and the need for an access sheath, the obturator with its tapered tip (approximate shaft diameter of 11–13F) can be used to softly dilate the stricture.

Irrigation systems

Irrigation under pressure, always using normal saline at body temperature, is required to actively create a space to work in. Normal saline is the irrigant of choice because there is always a risk of absorption from pyelolymphatic or pyelovenous backflow or from ureteral perforation. Irrigation with glycine (or water) is no longer needed as since the advent of the holmium laser, which allows for fulguration and ablation of tissue, electrosurgery has been made obsolete.

Different irrigation systems have been described, the most common of which uses a pressure bag. A Level 1 System (Level NORMOFLO Irrigation Warming Set, Smiths Medical ASD, Rockland, MA, USA) delivers precision control of the irrigant and warms it to body temperature. Manually inflated reusable pressure bags can also be used. Another option is a control pump syringe or a hand-held bulb pump attached to gravity irrigation. In this case, the operating surgeon or their assistant provides pressure irrigation during critical parts of the procedure, with the obvious disadvantage that constant visualization is not maintained. A hands-free irrigation system that is activated by a foot pedal and another that requires a hydraulic pump have also been used [2, 13].

Endoscopes and video equipment

Semi-rigid ureteroscopes contain fiberoptic bundles instead of the classic rod –lens system, which allow a small amount of axial bend. They have a tapered profile, smallest at the tip (6–8.5F) and progressively widening to a larger shaft by the eyepiece (7.5–11.2F).

Semi-rigid ureteroscopes are preferred over their flexible counterparts whenever possible, and especially in the distal ureter because of their larger working channels, faster irrigation, better and bigger image quality, and durability. Moreover, flexible ureteroscopes are difficult to use in the distal ureter because of their lack of "purchase" of this ureteral segment.

In 2006 the world's first semi-rigid video ureteroscope was introduced. The image is captured by a charged coupled device (CCD) chip at the endoscope's distal tip and carried by wire to the control box. This control box acts both as the light and camera boxes of the standard set-up. This design obviates the need to attach a camera to the eyepiece, resulting in an easier set-up and a lighter hand piece. There is no need for a separate camera, camera cord, light box, and light cord. When compared to standard semi-rigid ureteroscopes, the image of videoendoscopes is larger and without the honeycomb effect due to the absence of image-carrying fiberoptic bundles.

Step-by-step distal ureteroscopic access

Cystoscopy and guidewire placement

Flexible or rigid cystoscopy can be used for a systematic assessment of the bladder mucosa to rule out bladder pathology and for initial guidewire placement in the ureter. Rigid (rod–lens) cystoscopes offer better image quality and irrigation capabilities, and are easier to operate than standard flexible equipment. However, in patients with prominent prostatic median lobes or high-riding bladder necks, visualization of the ureteral orifice may prove difficult with a rigid cystoscope and may require the use of a 70º lens and an Albarran deflector. Alternatively, a flexible endoscope can be used.

Ureteroscopy usually begins with a retrograde pyelogram to determine the upper tract ("road map") ahead. However, if the semi-rigid ureteroscopy is performed for a distal stone and there is no need for ureteral dilation, we prefer to insert a 0.035-inch hybrid wire up into the ureter until it is coiled in the kidney, obviating the need for a pyelogram out of concern that it may produce proximal stone migration.

Proper guidewire position is always confirmed fluoroscopically. This safety wire should be kept in place for the duration of the case as it will prove useful to deploy a stent in the event of a perforation or to regain access into the more proximal collecting system in the setting of bleeding. If there are doubts as to the correct placement of the wire, or if the wire does not progress proximally, it is exchanged for a straight open-ended 5F ureteral catheter through which a gentle (low-pressure) retrograde pyelogram is performed with diluted contrast. If the wire is bouncing against an obstruction or

stone and not progressing forward, a hydrophilic wire, straight or angled tip, is deployed through the open-ended stent, used as a backing, to negotiate the wire past the restriction. In the event that this fails, the open-ended stent can be exchanged for an angled stent, which in combination with a hydrophilic angled wire exponentially increase the angles of attack of the tip of the wire against the obstructing stone.

If the retrograde pyelogram shows extravasation, the ureteroscopy should be stopped and a stent deployed. If the extravasation occurs prior to having a safety wire in the kidney, either because it could not be manipulated into the intrarenal collecting system or because access was lost during the procedure, and proximal access cannot be regained expeditiously, percutaneous nephrostomy tube drainage is indicated to avoid ongoing extravasation and to relieve the obstruction.

Ureteroscope insertion

After proper guidewire placement, the semi-rigid ureteroscope is advanced alongside the wire into the bladder. It is useful to find the guidewire at the bladder neck and follow it to the ureteral orifice since the field of view is much smaller than with the cystoscope (see Video 46.1). The orifice is usually tented up by the wire. The tip of the scope is then positioned "opposite" the wire to gain access (see Video 46.2). Positioning the scope on the wrong side of the wire will preclude ureteral entry.

The beveled tip design of modern semi-rigid ureteroscopes allows for relatively easy access across the ureteral orifice. The endoscope is then advanced only when the instrument slides freely and there is a clear field of view. If resistance to the passage of the scope occurs, the scope is pulled back, rotated, and reintroduced (see Video 46.3). If the endoscopic image is not clear, the scope is slightly withdrawn as it may be against the ureteral mucosa.

Most often semi-rigid ureteroscopy does not require orificial dilation; however, when needed it is accomplished with a balloon dilator, coaxial ureteral dilators, or an access sheath. In 1991 Garvin and Clayman showed no clinical consequences from balloon dilation of the ureteral orifice to 24F [14]. Currently, with the newer and smaller fiberoptic ureteroscopes, ureteral dilation is probably not needed beyond 12–15F.

Ureteral dilation

If the surgeon anticipates during cystoscopy/retrograde pyelography that the ureteral orifice or ureter needs to be dilated, a hybrid (combined) or super-stiff wire is deployed and balloon dilation under endoscopic and fluoroscopic vision is performed (see Videos 36.4–36.7). The balloon is fed over the wire and through the cystoscope, positioned straddling the narrow segment, and then slowly inflated to visualize the contour of the stricture as the balloon "waists" around it before it becomes fully inflated (Figure 36.1; see Video 36.4) Alternatively, coaxial ureteral dilators can be used over a wire under fluoroscopic vision.

Ureteral access in patients with altered anatomy

Ureteral reimplant and ureteral J-hooking

Occasionally the trigonal anatomy is distorted and the ureteral orifices are not orthotopically located, as in patients with previous ureteral reimplantation. The Glenn-Anderson technique advances the ureteral orifice distal to its native position, while the Cohen technique crosses the orifice to the opposite trigone. The Cohen technique is perhaps the most popular today; however, it has the potential disadvantage of hindering future retrograde ureteroscopic access to the kidney [15].

Wallis *et al*. described a technique that permits catheterization and ureteroscopy after a Cohen reimplantation. After cystoscopic access and visualization of the ureteral neomeatus, an angled-tip ureteral catheter is inserted via the cystoscope and aimed at the ureteral orifice. Grasping the catheter at its hub allows 360º rotation of the tip. Next, a hydrophillic angled-tip guidewire with a torque device attached is passed through the catheter and directed into the orifice. The torque device also permits 360º rotation of the guidewire tip. The combination of the curved catheter and angled guidewire permits eventual cannulation of the reimplanted ureter. The wire is then negotiated up the ureter. A catheter is passed over the wire into the ureter and a retrograde pyelography is performed, confirming proper positioning. A super-stiff wire is then deployed which may straighten the ureter to allow rigid or flexible ureteroscopy using standard techniques [16].

A similar technique of cannulation with a hydrophillic wire, later exchanged for a super-stiff wire to rectify the ureteral alignment and facilitate ureteroscopy, can be employed to deal with J-hooking of distal ureters, transplant ureters, or ureters reimplanted into a psoas hitch or a Boari flap. A tortuous, redundant ureter can similarly be straightened to facilitate flexible ureteroscopy. However, care needs to be exercised to avoid excessive torquing of the semi-rigid ureteroscope when advancing it beyond surgically altered anatomy, and a low threshold to switch to a flexible endoscope should exist.

If ureteroscopy fails due to surgically altered anatomy of the distal ureter, a percutaneous approach for antegrade endoscopy may be required.

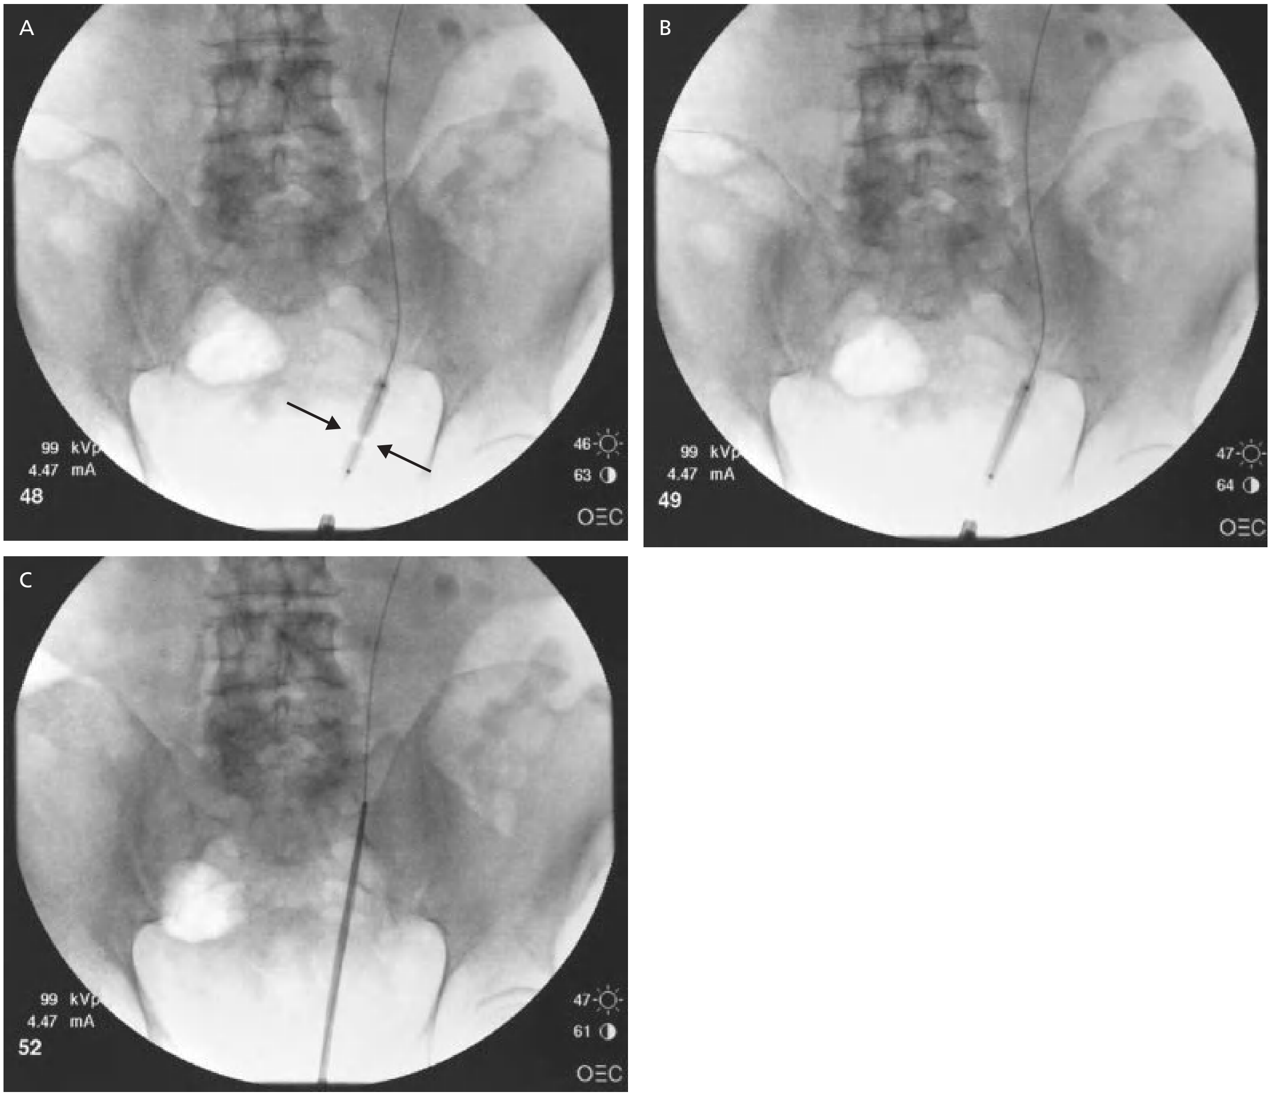

Figure 36.1 (A) Balloon is slowly inflated with dilute contrast solution, and a "waist" forms around the stricture (arrows). (B) Fully inflated balloon. (C) Easy ureteroscopic access beyond stricture.

Urinary diversion

Cannulation of ureters implanted into urinary diversions follows the same previously described technique. However, in patients with Studer or Hemi Kock neobladders, upper tract access with a semi-rigid ureteroscope is usually not feasible due to the 3D spatial relationship between the ureteral neomeatus and the bladder neck. Continent catheterizable diversions are probably best approached with a flexible cystoscope to avoid injury to the continent mechanism through excessive torquing of a rigid device against it. Ileal conduit diversions usually allow cannulation of the anastomoses with a rigid cystoscope unless an excessively long bowel segment was used for their construction.

Finding the ureteroenteric anastomoses and obtaining ureteral access is probably the most challenging part of the procedure. Knowledge of the type of diversion and in the case of a neobladder, whether it has an afferent limb, will greatly improve the ability of the surgeon to find the anastomoses. However, it may still be difficult to find the reimplanted ureters due to the presence of mucus, occasionally large capacity of the diversion, lack of landmarks, and a constantly moving target due to peristalsis.

A combined antegrade and retrograde approach has been described to facilitate retrograde access to the ureteroenteric anastomosis and ureter in diverted patients. A previously placed small-bore percutaneous nephroureteral stent with its distal tip in the urinary diversion is exchanged for a super-stiff wire and cystoscopically retrieved from the diversion, thus providing through-and-through access, which enables rapid and easier retrograde identification of the anastomosis and segment

of interest in the upper tract. Furthermore, this approach allows the use of larger semi-rigid or flexible endoscopes in conjunction with more efficient fragmentation devices, resulting in enhanced vision from better irrigation [17].

Ureterocele

A single-system ureterocele usually manifests in adults. It is almost always intravesical and occupies the proper trigonal position. The degree of obstruction is probably not significant in most adult cases; however, patients may present with an obstructing ureterovesical junction (UVJ) stone. Since most single-system ureteroceles have pinpoint orifices, access may require dilation or incision of the ureterocele before ureteroscopic access, usually through a transverse incision as close to the bladder floor as possible, through the full thickness of the ureterocele wall. An incision low on the ureterocele lessens the chance of postoperative reflux [18].

Stone impaction at the ureterovesical junction

Occasionally, a stone is found impacted at the ureteral orifice, which becomes edematous. In this scenario, and after deployment of a safety wire, the stone is gently pushed back with the tip of the ureteroscope into the dilated intramural ureter, or laser fragmentation is begun from the bladder side to dislodge the stone and enter the ureter. On occasions, a 12 o'clock holmium laser ureterotomy, incising the ureteral orifice over the stone, is required.

Ureteral trauma

The ureteral segments more prone to injury during ureteroscopy are at the UPJ and UVJ, where the muscular backing of the ureter is thinnest, and at the pelvic brim due to the angulation of the ureter over the psoas muscle [19]. In special situations, where the ureteral orifice or mucosa are edematous and friable secondary to unsuccessful traumatic wire deployments or stone impaction, or in the setting of an ureteral false passage, access requires driving the scope to the traumatized area and deploying a wire under direct ureteroscopic vision. If there is significant ureteral trauma, multiple fluoroscopic attempts with catheters and wires may traumatize the area further and ultimately lead to failure to deploy a wire in the kidney.

For this reason, if the patient has a previously placed indwelling ureteral stent, and especially if there is periureteral orifice edema, we prefer to deploy the safety wire alongside the stent prior to removing it. This maneuver facilitates the visualization of the orifice and may avoid an intramural ureter false passage.

Conclusions

A thorough knowledge of the endoscopic equipment and disposable instrumentation is mandatory for a successful ureteroscopy. Atraumatic guidewire access maintained throughout the duration of the case allows for smooth navigation in difficult cases and provides an exit strategy that allows return at a later date. The constant evolution of endoscopic equipment and instruments is enabling the realization of increasingly more challenging procedures.

CHAPTER 37

Access to the Ureter: Flexible Ureteroscopy

Ojas Shah & Elias Hyams
New York University School of Medicine, New York, NY, USA

Introduction

Retrograde flexible ureteroscopy (URS) is a widely utilized technique for evaluation and treatment of upper urinary tract pathology, both benign and malignant. Technologic improvements (e.g. smaller caliber ureteroscopes, greater active deflection) have expanded the role of flexible URS for the management of these processes, including urolithiasis, ureteral stricture disease, and upper tract urothelial or transitional cell carcinoma (TCC). Obtaining ureteral access for flexible URS is typically straightforward, but can be challenging depending on anatomic and disease factors.

In this chapter, we review the preoperative evaluation of patients undergoing flexible URS, preparation of the operating room, and techniques for standard and difficult access. We also review the role and technique for ureteral access sheath (UAS) placement to enable rapid and safe re-entry into the ureter, particularly in the management of stone disease.

Preoperative evaluation

A thorough history and physical examination should be performed preoperatively. History details that may illuminate an increased risk of difficult access should be elicited. Advance knowledge of these risk factors allows for preoperative planning as well as appropriate counseling of patients regarding risks and the possibility of failed access.

Specific aspects of the past medical history should be emphasized. History of benign prostatic hyperplasia and/or bladder outlet obstruction should be elicited. A large occlusive prostate may impede bladder access and, if friable, may impair visualization secondary to bleeding. A large intravesical median lobe may obscure visualization of one or both ureteral orifices. Chronic bladder outlet obstruction may also cause bladder trabeculations or diverticula, which may distort intravesical anatomy and hinder the identification of the orifices. A history of pelvic or retroperitoneal radiation, or of trauma, may increase the likelihood of scar tissue formation, leading to tissue or anatomic distortion. Abdominal aortic aneurysms should be noted as they may cause extrinsic compression of the ureter and/or deviation. Patients with retroperitoneal fibrosis, which may be secondary to numerous processes (e.g. trauma, medication-related, idiopathic), may also have narrowing of the ureter.

Surgical history pertaining to the urinary tract should be reviewed. Prior open or endoscopic interventions may increase the risk of ureteral stricture disease and thus hinder access. Prior surgery may alter anatomy, including ureteral reimplantation with neoureterocystotomy. Reimplantation may also convey risk of vesicoureteral anastomotic stricture or reflux. Review of prior operative reports may guide access regarding location of the new orifice. Prior urinary diversion surgery similarly requires ureteral reimplantation, which can make a retrograde approach technically challenging and

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

has a potential risk of ureterointestinal anastomotic stricture. Finally, prior abdominopelvic (e.g. colorectal surgery, hysterectomy/salpingo-oophorectomy) or retroperitoneal surgery (e.g. abdominal aortic aneurysm repair) can lead to stricture disease from injury to or devascularization of the ureter.

Other pertinent details of the patient history include use of anticoagulants or antiplatelet agents. Often these agents can be stopped in consultation with a cardiologist or internist; however, in certain instances patients cannot safely stop these medications and the procedure should be performed as atraumatically as possible. Ureteral dilation techniques should be avoided when operating on patients who are actively anticoagulated. If there is difficulty with access to the ureter, a ureteral stent should be placed to allow for passive dilation prior to definitive treatment. There is evidence that ureteroscopic interventions in patients taking these agents are safe, particularly in the management of stone disease [1].

Another important detail of the history is whether a patient demonstrates signs or symptoms of urinary tract infection, or risk factors for colonization of the urinary tract. Patients should be treated to clear an acute infection prior to surgery. Those with colonization should be placed on culture-specific antibiotics prior to surgery to minimize risk of urosepsis with instrumentation.

Informed consent is necessary prior to proceeding to the operating room. Risks and benefits of the proposed surgery should be discussed with the patient preoperatively; these include but are not limited to bleeding, infection, injury to the kidney, ureter, and adjacent structures, and ureteral stricture. Patients should be informed of the risk of failed access and the possible need for ureteral stent placement with abortion of the procedure and/or percutaneous nephrostomy tube placement. The more thoroughly patients are counseled preoperatively, the greater trust will persist postoperatively if these situations occur, and subsequent counseling of the patient will be facilitated.

Preparation of the operating room

Prior to flexible URS, the operating room staff should confirm that all potential instruments and disposable equipment are available, and the surgeon should confirm that this equipment is correct (Table 37.1). The steps of the procedure should be anticipated and the scrub table organized to ensure a smooth succession of events. Additional equipment for difficult access cases may also be required at the discretion of the surgeon (Table 37.1). If access fails, the patient may require a percutaneous approach or nephrostomy tube, which can be placed by the urologist or interventional radiologist.

Table 37.1 Equipment for standard and difficult ureteral access for flexible ureteroscopy.

Standard access
Rigid cystoscope (30 and 70° lens) with light cord, camera, and irrigation fluid (Albarran bridge if desired)
Nitinol guidewires: 0.035 or 0.038 inch [hybrid guidewire if desired – polytetrafluoroethylene (PTFE):nitinol with hydrophilic tip]; at least two wires (working and safety)
Dual-lumen or coaxial catheter
Contrast medium (50:50 ratio with saline) for retrograde pyelography with syringe for injection
If retrograde pyelogram needed before access to upper tract performed → 5F or 6F open-ended catheter or cone-tip catheter
Ureteral access sheath at the discretion of the surgeon
Flexible ureteroscope (tested to ensure clear lens and adequate deflection)
Ureteral stent (double-J or pigtail) with different calibers and lengths (or multi-length)
Difficult access
Flexible cystoscope
Semi-rigid ureteroscope
Angiographic catheters with an angled tip
Balloon dilators
Serial dilators
Angled-tip and straight hydrophilic guidewires (with torque device if needed)
Various size wires (e.g. 0.025 inch)

Balloon dilators are useful for accessing anatomically tight or strictured segments of ureter. Dimensions of balloon dilators vary by manufacturer; we typically use 4-, 6- or 10-cm dilators with 12–15F balloons inflated to 12 atm. Dimensions of available standard ureteral balloon dilators include balloon lengths of 4–10 cm, inflated balloon diameters of 12–18F (4–6 mm), and dilation pressures up to 30 atm.

Fluoroscopy (C-arm or table) is required to guide positioning of wires, catheters, and ureteral access sheaths, and to enable retrograde pyelography. Placement of the flexible ureteroscope can be performed with fluoroscopic guidance over the working guidewire up to the level of disease, e.g. stone or stricture. Fluoroscopy is also useful for identification of radio-opaque stones and following the fragmentation of a stone during laser lithotripsy. The surgeon should confirm that fluoroscopy is correctly positioned and can be easily manipulated prior to surgery.

Standard retrograde access for flexible ureteroscopy

Depending on institutional protocol, the surgical site (i.e. side for ureteroscopy) should be marked by the operating surgeon.

The type of anesthesia will depend on a detailed conversation between the anesthesiologist, surgeon, and patient, and may be influenced by numerous factors (e.g. cardiopulmonary status of the patient, need for apnea during the procedure, patient preference).

The patient is positioned in the dorsal lithotomy position, and prepped and draped in standard sterile fashion. A single dose of prophylactic antibiotic is administered prior to the procedure if the preoperative urine culture is negative. If the patient has a positive preoperative urine culture, they should be treated with a full course of culture-specific antibiotics prior to intervention. Sequential compression devices should be placed on the patient's lower extremities prior to induction of anesthesia. Alternatively, deep venous thrombosis prophylaxis can be given with subcutaneous heparin or low molecular weight heparin.

The bladder is initially entered with a rigid cystoscope. After cystoscopic evaluation of the bladder, the relevant ureteral orifice is identified and cannulated with a guidewire. The guidewire may advance through the end of the rigid cystoscope directly into the orifice, or a 5F open-ended catheter may be required to provide the correct angle for intubation of the orifice. Keeping the camera stationary, the scope can be rotated to change the angle at which the wire advances. When advancing the wire into the orifice, it is important to ensure the end of the cystoscope sits directly at the orifice to prevent buckling or curling of the wire in the bladder. We prefer to use a 0.035 or 0.038 inch x 150 cm hybrid guidewire because its flexible, hydrophilic tip minimizes trauma to the upper urinary tract, it allows easy manipulation around upper urinary tract stones and obstruction, it is kink-resistant, and it has sufficient rigidity to act as a working wire. The wire is advanced gently under fluoroscopic guidance into the kidney (Figure 37.1), minimizing trauma to the collecting system which can lead to mucosal bleeding and obscure visualization. This is particularly important when URS is being performed for evaluation of upper tract TCC as wire trauma may confound evaluation of TCC or carcinoma *in situ*. Also, patients who are anticoagulated or have bleeding diathesis may have significant bleeding from wire trauma, thus extra caution is necessary in these patients.

If the wire does not advance easily, a retrograde pyelogram should be performed over an open-ended catheter (or with the use of a dual-lumen catheter placed over the initial guidewire) to delineate the ureteral anatomy (e.g. evaluate for presence of ureteral tortuosity or obstruction). Methods of addressing an inability to advance the initial wire are discussed below.

With the first wire in the correct position, the bladder is emptied through the cystoscope (side port or sheath) to maximize the likelihood of successful passage of a catheter and/or ureteroscope through the intramural ureter. At this time, we recommend placement of a

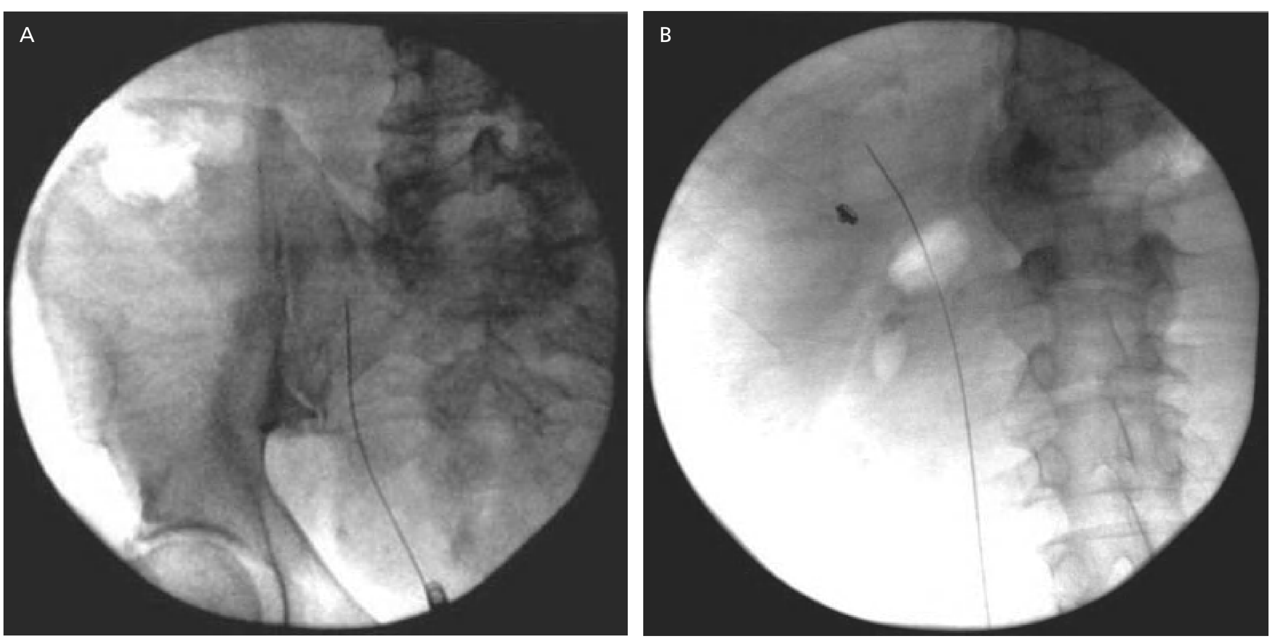

Figure 37.1 Guidewire advanced to (A) mid ureter and (B) level of kidney.

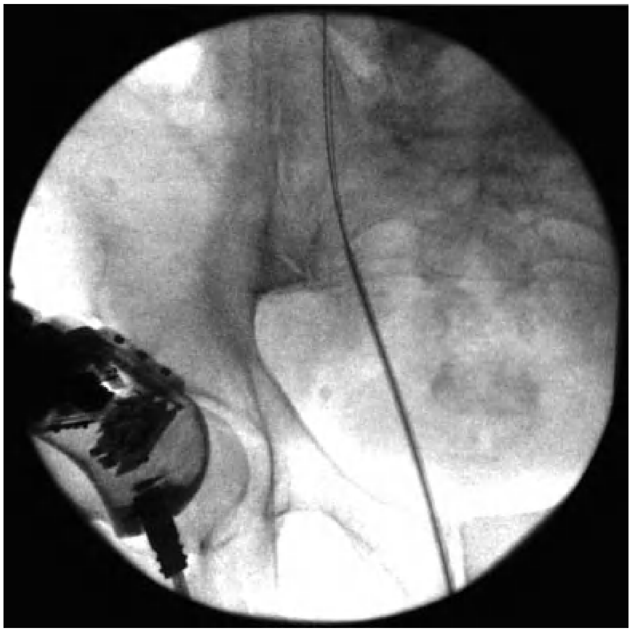

Figure 37.2 Dual lumen catheter with two wires advanced.

second wire as a safety wire. A safety wire allows for ureteral stent placement at any time should there be iatrogenic injury or an inability to proceed. It will also prevent loss of access to the upper urinary tract during the surgery. A dual-lumen or coaxial catheter can be placed over the initial wire into the distal ureter under fluoroscopic guidance and the second wire is advanced alongside the first wire to the renal pelvis (Figure 37.2). A retrograde pyelogram can be performed through the dual-lumen catheter prior to second wire placement if it has not been performed earlier. Alternatively, a second wire can also be placed under direct vision through the cystoscope adjacent to the first wire. The benefit of using a dual-lumen 10F catheter or 8/10F coaxial catheter is that these gently dilate the distal ureter, allowing for easier passage of the flexible ureteroscope.

After the second wire is placed, the dual-lumen catheter is removed and one wire is secured to the drape as a safety wire. The safety wire should be secured away from the immediate surgical field to minimize risk of dislodgement. At this time, the flexible ureteroscope is placed over the working wire and advanced to the level of interest under fluoroscopic guidance.

Difficult retrograde access for flexible ureteroscopy

Certain situations can confound efforts to obtain ureteral access. Below we discuss methods of troubleshooting these scenarios.

Ureteral orifice(s) cannot be visualized

There are various reasons why ureteral orifices may not be readily visible on cystoscopic evaluation: distorted anatomy (e.g. bladder trabeculations, mucosal edema, neoplasm), obscured anatomy (e.g. intravesical median lobe), congenital anomalies (e.g. ureteral ectopia), or prior surgery (e.g. ureteral reimplantation, resection). If there is anatomic distortion, an ampule of indigo carmine or methylene blue can be administered intravenously and efflux of dye can be sought. It is important that patients are well hydrated, have adequate renal function, and do not have significant obstruction of the ipsilateral kidney to ensure the dye is rapidly excreted. Intravenous furosemide can be concomitantly administered to expedite excretion from the kidneys. If there is obscured anatomy from a large median lobe, a rigid cystoscope with a 70º lens may enable identification of the orifice. A flexible cystoscope can also be utilized to identify the orifice beneath the lobe and in patients with a very high riding bladder neck, which prohibits bladder access with a rigid scope. Accessing the orifices with flexible cystoscopy can be technically challenging as irrigant flow and visibility are inferior to those with a rigid scope, and achieving the correct angle for access of the orifice may be difficult. Additionally, the use of an Albarran deflecting bridge or an angled-tip angiographic catheter (e.g. 5F Berenstein catheter) can help deflect guidewires into a ureteral orifice that is at an acute angle or distorted secondary to bladder and prostate anatomy.

If the orifices cannot be found, there should be consideration of congenital anomalies or prior surgical history that may have altered their position. Preoperative imaging can be helpful in delineating upper tract anatomy, including ectopic ureters; urographic imaging is particularly helpful. Clinical history may reveal the possibility of variant or altered anatomy, e.g. history of vesicoureteral reflux disease, incontinence, or chronic pyelonephritis. Review of prior operative reports may provide guidance regarding location of ureteral orifices after ureteral reimplantation.

Guidewire will not advance through the ureteral orifice

The tip of the cystoscope should be placed immediately at the ureteral orifice to prevent kinking of the wire. A 5F open-ended catheter can be placed through the cystoscope and used as a guide and/or support for the wire, creating the desired angle for access and preventing kinking. An angiographic catheter can also be used for this purpose. Use of an open-ended catheter also allows for retrograde pyelography; the catheter can be placed at the orifice and contrast injected to determine if there is patency of the orifice and/or distal ureter.

With the open-ended catheter at the orifice, either a straight or angled-tip guidewire (nitinol or hydrophilic) can be gently advanced and manipulated. If there is concern for a stricture at the orifice or an impacted stone, a rigid ureteroscope can be used to directly access the orifice and wire placement under vision can be attempted. If there is an impacted stone, it can be treated to expose the proximal lumen and enable wire placement; however, without a safety wire this should be done with care. If wire access cannot be achieved and there is clinically significant obstruction, the procedure should be aborted and a percutaneous nephrostomy tube placement should be performed.

Guidewire will not advance through the ureter to the kidney

If the wire has successfully accessed the ureteral orifice but will not advance past a level of ureter, an open-ended catheter should be placed over the wire and a retrograde pyelogram performed to ensure there is no stricture, ureteral injury/false passage, obstructing lesion or stone, or severe tortuosity/J-hooking. This can also be performed with a dual-lumen catheter which can be advanced over the guidewire that has already been placed. If the open-ended catheter will not easily advance over the wire, it is possible that the wire has been placed submucosally, and it should be withdrawn and replaced in the true lumen. If there is a transition point for obstruction or severe tortuosity, the open-ended catheter can be placed to that level to prevent buckling of the wire as it is advanced. An angled-tip hydrophilic guidewire can be useful if there is a severe angle to negotiate. Surgeon experience is critical to understanding how much pressure can be safely applied while advancing the wire. If there is obstruction and concern for a pinpoint stricture, an experienced surgeon may place the ureteroscope over the wire to the level of interest and then attempt to advance the wire under vision. Also, if there is a severely impacted stone and inability to obtain proximal access with a wire, an experienced surgeon can attempt to treat the stone with caution to expose the proximal ureter and enable safety wire placement. Importantly, without a safety wire in place these maneuvers can worsen obstruction, cause damage to the ureter without an option for immediate stent placement, and necessitate percutaneous nephrostomy tube placement.

If a guidewire cannot traverse the level of obstruction, the procedure should be aborted and nephrostomy tube placement should be considered. If access is achieved but traumatically, a retrograde pyelogram should be performed and ureteral stent placement with deferral of the procedure should be considered if there is extravasation.

Initial guidewire placement was successful, but a coaxial/dual-lumen catheter or ureteroscope will not advance through the ureteral orifice

First ensure that the bladder is empty; it is not uncommon to neglect to empty the bladder before removing the cystoscope. Careful twisting and advancement of the dual-lumen catheter, which has a tapered tip, can often enable access into the distal ureter. While advancing the catheter over a wire, it is important that the wire remains stationary (secured by the surgeon or an assistant) to allow the catheter to advance without buckling. Inability to advance the catheter may indicate anatomic narrowing or stricture at the ureteral orifice. This necessitates a decision whether a ureteral stent should be placed and the procedure deferred for 5–7 days for passive dilation of the ureter, or whether ureteral dilation should be performed. Our algorithm usually begins with retrograde pyelography with a dual-lumen catheter. If multiple areas of the ureter appear narrow in addition to the ureteral orifice, we place a ureteral stent and return to the operating room in approximately 1 week. If the ureteral orifice or intramural tunnel appears to be discretely narrow or strictured, several dilation techniques are available.

Ureteral balloon dilation can be performed by advancing a balloon dilator over the wire and ensuring the radio-opaque markers span the orifice (Figure 37.3). The balloon is filled with contrast and held at 12 cmH_2O for approximately 1 min. The balloon is then deflated and removed, and the dual lumen catheter is advanced over the wire to allow for passage of the second working guidewire (if not already placed). The ideal balloon dilator for this region is 4 cm x 12F, which minimizes trauma to the ureter and the risk of extravasation, and has not been shown to cause ureteral structuring [2]. Active dilation can also be performed with serial dilators (e.g. Nottingham dilators). Finally, dilation can be performed under direct vision with a semi-rigid ureteroscope.

While dilation may enable access to the ureter, it can be traumatic and cause edema and/or urinary extravasation; thus, it is important to ensure a ureteral stent is placed at the end of the case if dilation is performed. When treating a stone, it is important to be aware if a distal stricture is present as residual fragments may not pass after stent removal, and risk of an obstructing fragment or steinstrasse may be increased. A ureteral stricture should be ideally treated prior to the treatment of a more proximal stone, and allowed to heal prior to lithotripsy. Concomitant treatment can increase the risk of submucosal stones or stone granuloma formation, which can lead to stricture disease.

If a dual-lumen catheter will not advance despite balloon dilation, or if balloon dilation is contraindicated

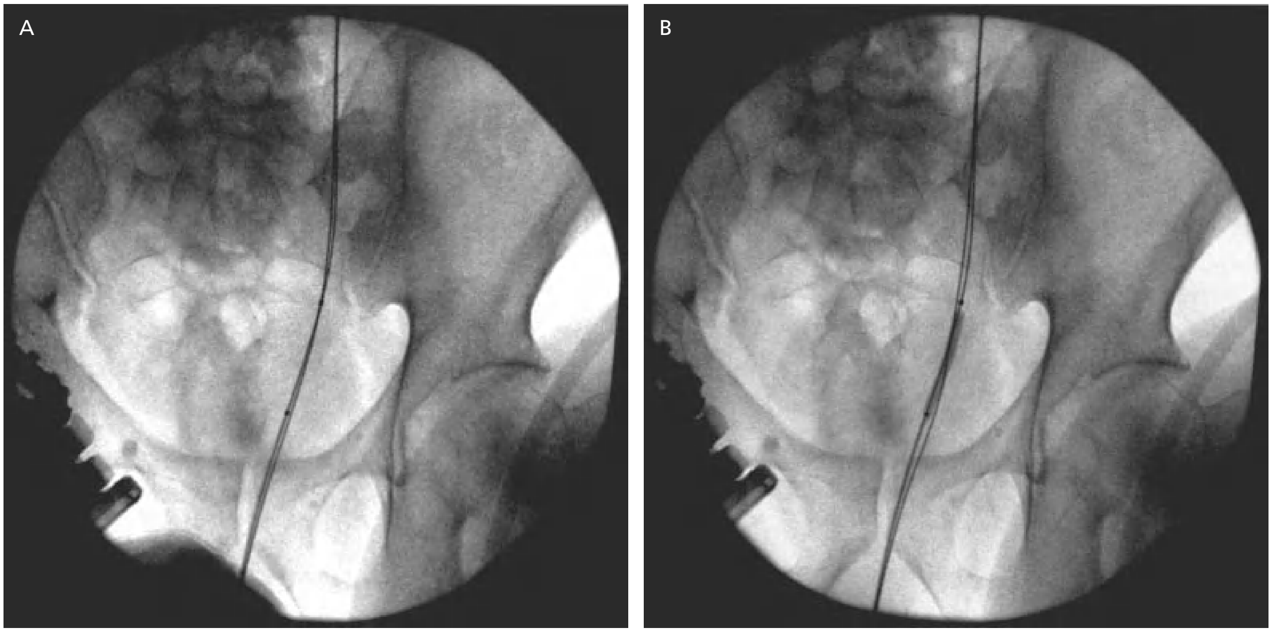

Figure 37.3 Balloon dilator. (A) 4 cm × 12F ureteral balloon dilator positioned in the intramural tunnel. –(B) Balloon expanded to dilate distal ureter/intramural tunnel.

(e.g. bleeding diathesis), a ureteral stent should be placed to allow passive dilation of an anatomically tight ureteral orifice and healing of a dilated stricture, and/or to relieve acute obstruction. Without a safety wire it is typically not recommended to proceed with ureteroscopy when an intervention is anticipated, except in the hands of experienced endourologists. With the newer generation flexible ureteroscopes, ureteroscopy has been demonstrated to be safe without the use of a guidewire ("wireless") [3].

If a wire has passed but even a stent will not advance through the orifice, a small open-ended catheter can be advanced to the kidney and secured to the Foley catheter; this can allow for retrograde pyelography at the time of nephrostomy tube placement to facilitate placement of the tube, particularly if there is no severe dilation of the collecting system.

With safety and working wires in place, the flexible ureteroscope may not advance through the ureteral orifice or a segment of the ureter. The techniques discussed above may apply here (e.g. emptying the bladder, holding the wire tautly, balloon dilation). If the ureteroscope will not advance within the ureter, retrograde pyelography should be repeated to ensure there is no ureteral injury. If there is an obstructive lesion, the ureteroscope can be advanced to the level of the lesion and the area examined. With a safety wire in place, the lesion can be treated (e.g. laser lithotripsy of a ureteral stone, endoureterotomy). At any time, if the ureteroscope will not advance despite these efforts, ureteral stent placement can be performed and interval surgery planned.

If at any stage there is evidence of ureteral perforation with extravasation, a ureteral stent should be placed and the ureter should be allowed to heal before reintervention. There may be new stricture formation from a ureteral injury, and this should be investigated at the time of follow-up surgery. If ureteral avulsion occurs, stent placement should be performed if possible, and the procedure should be aborted. Percutaneous nephrostomy tube placement will likely be necessary, and ureteral reconstruction may be considered in the same sitting if severe injury has occurred to a focal segment (e.g. ureteral reimplantation for an avulsion at the level of the bladder). If more complex reconstruction is required in delayed fashion, percutaneous nephrostomy tube placement should be performed.

During manipulation of multiple wires and catheters, patients can develop bleeding from the upper tract that may obscure visualization. If visualization is significantly compromised, the procedure should be aborted and a ureteral stent placed. Bleeding from the upper tract will typically tamponade, and a stent will allow continued drainage of the kidney. Any uncorrected coagulopathy should be addressed. Severe persistent bleeding with clot retention and/or hemodynamic instability may require continuous bladder irrigation, blood transfusion, and consideration of angioembolization.

Finally, instrumentation of the urinary tract may cause urosepsis in a patient with active infection or colonization. This may occur despite the administration of prophylactic antibiotics, and in particular may occur in

patients with infected stones. If a patient develops hemodynamic instability during the procedure and there is consideration for urosepsis, a stent should be rapidly placed along with bladder drainage, and broad-spectrum antibiotics administered until culture results return. If there are signs of purulent urine when accessing the upper urinary tract, cultures should be obtained and the procedure should be aborted until cultures are negative. If this occurs, a ureteral stent (+ Foley catheter) should be placed to allow for drainage of the infected urine from obstructed renal moiety.

Ureteral access in patients with urinary diversion

Retrograde ureteral access in patients with prior urinary diversion surgery has been shown to be feasible and safe, though altered anatomy may increase the complexity of these procedures [4, 5]. Success of retrograde access may vary depending on the type of diversion and the indication for URS (ureteroanastomotic stricture disease vs surveillance or stone treatment), as well as the experience of the surgeon. In one retrospective study of these patients, 21 renal units underwent attempted retrograde access for diverse indications, and 75% of attempts were successful [4]. The success rate by type of diversion was 90% (9 of 10) for orthotopic neobladders, 73% (11 of 15) for ileal conduits, and 33% (1 of 3) for Indiana pouches. All attempts to access renal units for management of suspected upper tract malignancy were successful (13 of 13 patients, 100%), while attempts were less successful in patients with anastomotic stricture disease (5 of 10, 50%).

Prior to attempted retrograde access in these patients, operative reports should be reviewed to confirm the type of diversion, type of anastomosis (e.g. Bricker vs Wallace), and likely location of the orifices. A loopogram or cystogram can be performed prior to attempted access to determine patency and location of the orifices, though we do not believe this is routinely necessary. The bladder should be initially accessed with flexible cystoscopy, particularly for pouches or conduits; rigid cystoscopy can be considered in neobladders for direct access to the orifice, particularly in cases of ureteroanastomotic stricture. If a Studer neobladder has been performed, the afferent limb should be cannulated with the cystoscope and the orifices sought. If the orifices cannot be readily identified, methylene blue or indigo carmine can be administered intravenously to view efflux of dye. Cannulation of the orifice with a flexible guidewire is then attempted (Figure 37.4). If there is difficulty with cannulation because of the location or angle of the orifice, a 5F open-ended or Bernstein angiographic catheter with a straight or angled-tip hydrophilic guidewire can be used. We recommend routine placement of a safety wire in these patients as the initial access may be challenging.

Ureteral access sheaths

Ureteral access sheaths (UASs) are used to facilitate access to the ureter during flexible URS. They are used

Figure 37.4 (A) Orthotopic neobladder with Studer limb: access into the left ureter with guidewire. (B) Orthotopic neobladder with Studer limb: cystogram reveals right ureteral reflux (reproduced from Hyams *et al.* [4], with permission).

primarily for flexible URS/holmium laser lithotripsy to enable repeated entry into the ureter with extraction of fragments or to allow for passive egress of fragments. They may also be used for repeated biopsies and treatment of suspicious upper tract lesions (e.g. upper tract TCC). UASs have become standard practice in many institutions for treatment of stone disease in particular; however, routine use of UASs is still controversial based on concern for ureteral ischemia and questions regarding the ultimate benefit of UASs for clinical outcomes. Dimensions of UASs include 11/13F, 12/14F, or 13/15F diameter, and 25–55 cm length depending on the manufacturer.

Advantages of UASs are both theoretical and practical. UASs have been shown to decrease intrarenal pressure and may decrease pyelovenous and pyelolymphatic backflow, thus decreasing absorption of irrigant [6]. UASs improve irrigant flow, which may improve visibility and help to flush out small stone fragments, as well as decrease the need for emptying of the bladder during a protracted procedure. There is conflicting evidence regarding the impact of UASs on stone-free rates [7–10], but there are reports that these are improved (Table 37.2). There is also evidence that UASs decrease the cost and operative time for treatment of renal stones, but these studies have not been rigorously designed [8].

There have been objections to routine use of UASs, including risk of acute injury to the ureter and unknown long-term risk of stricture formation [11]. The latter appears low and consistent with standard URS; however, there have been no studies with long-term follow-up [9]. Nonetheless, there is *in vivo* evidence of transient ureteral ischemia with UAS use [12]. Furthermore, placement of a UAS may be impeded by a tight ureteral orifice, which may require balloon dilation to accommodate the access sheath; this may increase the risk of extravasation in addition to the time and cost of the procedure. Ultimately use of a UAS is at the discretion of the surgeon, and it may be beneficial on either a selective or routine basis.

Placement of a UAS is safest when performed over a working guidewire in the presence of a safety wire. The two components of an access sheath include an inner dilator and an outer sheath. Placement is facilitated by use of a working nitinol guidewire or Amplatz superstiff wire (not a hydrophilic guidewire), and the access sheath is placed as a unit to the desired level within the ureter, at which point the inner component is withdrawn (Figure 37.5). It is important that all components of the access sheath are wet as the surfaces are hydrophilic. The access sheath may be secured to the drape to ensure it does not dislodge. The level of

Table 37.2 Series of ureteral access sheath (UAS) use for treatment of upper tract calculi.

Study	Number of patients	Size of sheath	Number of balloon dilations (%)	Mean size of stone (mm)	Successful placement (%)	Stone-free rate	Complications

*Prospective randomized study of UAS (23) versus no UAS (21); there was no difference in stone-free rate (78.9% vs 85.7%; $P = .78$)
**Retrospective comparative cohort study of UAS (173) versus no UAS (83); stone-free rate was improved overall by use of a UAS (79% vs 67%; $P = .04$)

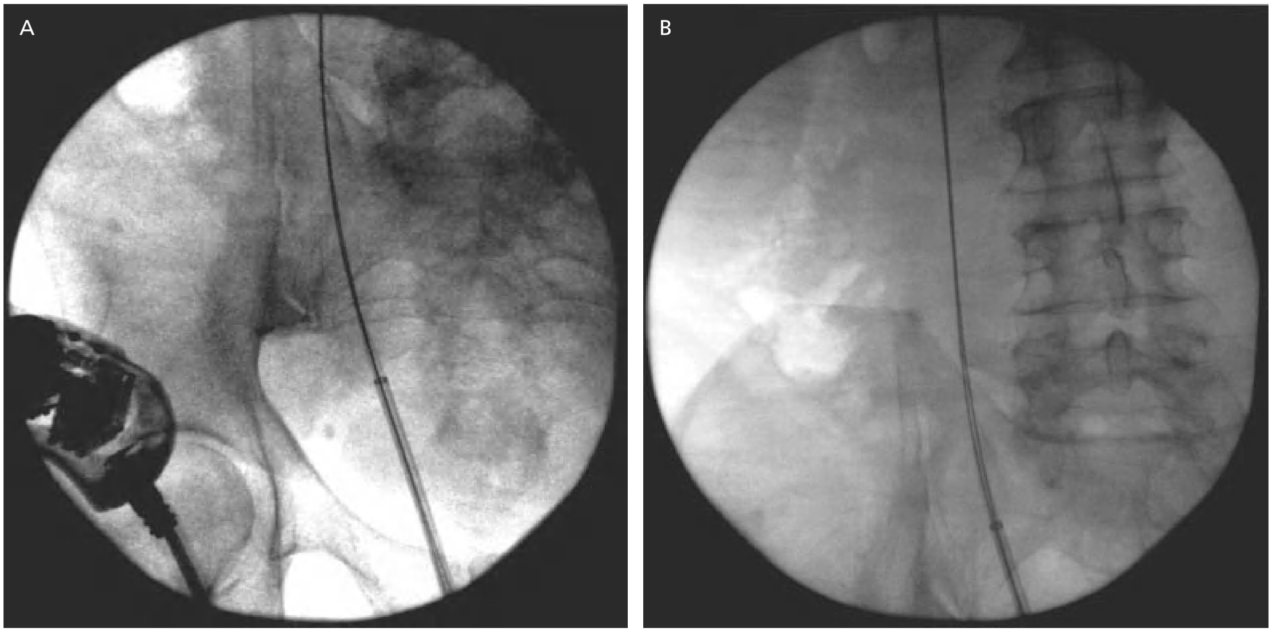

Figure 37.5 Ureteral access sheath placed in (A) distal ureter and (B) mid ureter.

placement depends on the clinical scenario; for a renal stone, placement in the proximal ureter is typical to protect as much ureter as possible during entry and re-entry.

Placement of a UAS can be compromised by an anatomically tight ureter or ureteral stricture disease. If the UAS cannot be placed through the orifice, balloon dilation may be performed. While some surgeons dilate the orifice on a regular basis for UAS placement, others will simply abort use of the sheath and continue without it. It has not been rigorously studied whether one approach is superior to the other from the standpoints of safety or stone clearance.

Finally, when placing an UAS, it important to be aware of small ureteral stone fragments that can be trapped alongside the sheath and are at risk for being pushed submucosally. If unrecognized this can lead to an impacted stone, or possibly a submucosal stone that can cause ureteral obstruction secondary to stricture formation.

We recommend placing a ureteral stent at the end of any procedure in which a UAS is used. Rapoport *et al*. retrospectively reviewed a series of consecutive patients who underwent URS for renal and ureteral stones, and found that use of a UAS without postoperative stenting significantly increased the risk of unplanned emergency room visits with increased emergency computed tomography (CT) scans, hospital readmission, and urgent decompression [13].

A radially dilating balloon UAS has recently been evaluated in the porcine model and appears to cause less urothelial damage compared to traditional UAS while enabling higher flow rate; this device still requires formal testing in human subjects [14]. Although preliminary evaluations have been favorable with regards to ease of use and success in placement in humans, no follow-up studies have been done with regards to clinical success, stone-free rate, operative time, and complication rates.

Conclusions

Access to the ureter for flexible URS is typically straightforward, but can be complicated by both anatomic and disease factors. Anticipation of the “next step” and planning for difficult access can maximize the likelihood of success in these cases. Repeated entry to the ureter for flexible URS can be facilitated by use of a UAS, though the precise risk-to-benefit ratio of UAS is not known.

CHAPTER 38

Ureteroscopic Management of Ureteral Calculi

Gautam Jayram & Glenn S. Gerber

Section of Urology, Department of Surgery, University of Chicago School of Medicine, Chicago, IL, USA

Introduction

Improvements in technology over the last 10–15 years have led to an increased ability to successfully manage ureteral calculi using a variety of methods. Although extracorporeal shock-wave lithotripsy (ESWL), antegrade percutaneous approaches, and laparoscopic ureterolithotomy are options, the mainstay in the treatment of patients with ureteral calculi continues to be retrograde ureteroscopic (URS) stone removal. Refinements in URS technology, as well as the development of improved laser techniques and advances in ancillary equipment, such as baskets, graspers, and others, have led to a situation in which almost all ureteral calculi can be successfully managed in a single procedure using URS.

Despite these advances, the selection of the single best approach to treat patients with ureteral stones remains controversial, especially given the complexity of today's changing healthcare environment. As there is increasing public focus on less invasive treatment strategies, it should be kept in mind that such approaches may in some cases lead to higher treatment failure rates with the need for secondary procedures. Additionally, a variety of economic factors have increased in importance in all areas of healthcare, and ultimately the most cost-effective approach to ureteral stones may be deemed best for all patients.

In this chapter, we will review the use of URS in relation to other treatment options for patients with ureteral calculi and discuss the wide variety of equipment and instruments that can be used with this procedure.

Treatment options

Many patients with ureteral calculi can be managed conservatively without immediate intervention. Observation alone is a reasonable approach for those patients with mild-to-moderate symptoms that can be controlled with oral analgesics, and those who do not have any factors that would warrant immediate intervention. These factors include infection, compromise of renal function, stone in a solitary kidney, nausea and vomiting preventing adequate hydration, and inability to adequately control pain. The likelihood of stone passage also has an important impact on the decision to proceed with intervention versus a period of observation with the hope for spontaneous stone passage. The most important factor in predicting whether a ureteral calculus will pass is the width of the stone. Location of the stone (proximal, mid or distal ureter) and impaction also have an effect on the relative likelihood of stone passage [1, 2]. In general, the accepted cut-off predicting a greater chance of stone passage is a size of 5 mm. Stones less than 5 mm in diameter have been reported to pass spontaneously in 70–90% of patients with distal stones and 30–80% of those with proximal stones [1]. In contrast, stones greater than 5 mm have a much lower likelihood of stone passage at 10–50% in general, with improved rates for those in the distal ureter [1, 2].

The decision to proceed with observation as an initial management approach is often largely based on patient preference. With the exception of the indications for

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

immediate intervention mentioned above, most patients can at least be offered the opportunity to pass the stone spontaneously. In our experience, some patients with ureteral calculi who have well-controlled symptoms react negatively if a urologist is “too aggressive” in recommending an immediate procedure, and may lose confidence in this urologist and end up seeking an alternative medical opinion. On the other hand, a frank discussion of the relative likelihood of stone passage is important in helping the patient decide whether immediate intervention is appropriate. Since an accurate prediction of the time to spontaneous stone passage is very difficult, patients must understand that the quoted statistics on stone passage are largely based on waiting times of up to 4–6 weeks. In many cases, due to work and personal considerations and the uncertain nature of when a stone will pass, patients may opt for stone removal rather than waiting.

The use of pharmacologic therapy to increase the likelihood of stone passage and decrease the interval until the stone passes has become increasingly popular [3–6]. Seitz *et al*. conducted a meta-analysis of published literature concerning the use of medical expulsive therapy in patients with ureteral stones [5]. For 47 randomized controlled trials they assessed the use of alpha-blockers and calcium channel blockers in patients with untreated ureteral calculi of varying sizes. Their results demonstrated that the use of either medication led to a higher and faster stone expulsion rate as compared to the control groups. In addition, treated patients had lower analgesic requirements, fewer episodes of colic, and fewer hospitalizations. Although other studies have not shown a difference in outcome when using alpha-blockers compared to no treatment in terms of stone passage rates [3], overall the risks associated with short-term use of these medications is minimal and it has now become an accepted practice to administer alpha-blockers in patients with ureteral stones. It is important that urologists continue to educate their colleagues in emergency medicine regarding this practice [4, 6].

Ureteroscopy

In performing URS, there are two basic choices of endoscopes, flexible and semi-rigid instruments (see Chapter 34). Semi-rigid instruments have fiberoptic bundles, range in size (external diameter) from 6.9F to 10F and may have single or dual working channels. There are several advantages associated with the use of semi-rigid ureteroscopes. In most cases, visualization is superior and it is easier for the operating urologist to control the instrument and manipulate accessory equipment such as baskets, graspers, etc. The diameters of the working channels of semi-rigid ureteroscopes are usually wider than those seen with flexible instruments, which allows for easier use of accessory equipment and improved irrigant flow. When removing stone fragments, repeated passage of the scope into the ureter is generally easier than when using a flexible instrument. In addition, semi-rigid instruments are often more durable than flexible instruments, leading to less breakage and lower cost associated with long-term use. As the diameter of these instruments has reduced, they can usually be safely passed into the ureter without the need for active ureteral dilation. Semi-rigid ureteroscopes are best suited for stones in the distal ureter below the crossing iliac vessels and may be more difficult to pass proximally in men, especially in those with large prostates.

The greatest technologic advances in URS over the last several years have come in the area of flexible instruments. Initially, lack of durability of flexible ureteroscopes was a significant problem, and expensive and frequent need for repair was the norm in most busy endourologic practices [7]. However, improvements have been made and today’s flexible instruments are generally less prone to breakage than earlier generations of scopes [8]. In addition, the degree of deflection (less important when treating ureteral stones than those in the kidney), size of the working channel, and overall visualization have also been significantly improved. A significant advance has been the development of fourth-generation digital flexible ureteroscopes (see Figure 34.9) [9]. Multescu *et al*. compared an Olympus digital ureteroscope and a standard Storz instrument and found that the digital scope had significantly greater maneuverability and visibility [9]. There was also less deflection loss with the digital scope when an accessory instrument was present in the working channel and irrigant flow was also superior. One disadvantage of the digital scopes are that they have a slightly larger tip that may also be more blunt, thus making access to the ureter and passage through narrow segments of the upper urinary tract more difficult. In most cases, we have found that it is necessary to have a ureteral access sheath in place in order to pass the digital ureteroscope into the ureter, whereas the standard flexible scope can be passed, if desired, without this sheath.

Overall, it is usually best to use a semi-rigid instrument if this can be safely passed to the level of the stone, even if the stone is located in the proximal ureter. As discussed above, the semi-rigid instrument is often easier for a single operating surgeon to use and usually allows for better visualization and irrigant flow. The semi-rigid scope is particularly well-suited for patients who have an indwelling stent prior to URS as this leads to passive dilation of the ureter, thus making passage of the instrument easier. However, if resistance is encountered, the semi-rigid instrument should never be forced more proximally in the ureter and instead switching to a flexible instrument is advisable.

Patient preparation and preoperative evaluation

Radiographic evaluation of the urinary tract is essential prior to URS and most patients will have undergone a noninfused computed tomography (CT) scan of the abdomen and pelvis. Although no contrast is used with this study, the ureteral anatomy can usually be well-defined. Additional information can be obtained at the time of the procedure by performing a retrograde pyelogram if necessary.

Some patients will initially present with urinary tract infection or urosepsis secondary to the obstructing ureteral calculus. This situation may be more commonly seen in diabetic patients or those who are immunocompromised. In this circumstance it is best to simply decompress the upper urinary tract with either ureteral stent placement or percutaneous nephrostomy tube insertion. Attempts to perform URS in the face of untreated or inadequately treated infection may lead to significant bacteremia with potentially disastrous complications. Even in patients without overt signs of infection or sepsis, it is appropriate to perform urinalysis and urine culture and ensure any infection is adequately treated prior to URS.

Informed consent prior to URS should include a discussion of the risks of ureteralinjury or perforation. Although most injuries can be managed simply with stent placement alone, there are rare circumstances in which more extensive treatment may be necessary. In addition, the risks of ureteral stricture and the need for treatment of this complication should also be discussed.

Surgical technique

URS is performed in most cases using general anesthesia. However, intravenous sedation alone or regional anesthetic techniques may be appropriate as clinical circumstances dictate. Allowance for adequate fluoroscopic visualization of the entire urinary tract is critical and provisions for radiographic monitoring should be made in all cases. In general, patients are placed in a dorsal lithotomy position with the contralateral lower extremity maximally abducted to facilitate access to the involved ureter. Broad-spectrum antibiotics are routinely administered prior to URS.

Increasingly, issues related to the use of anticoagulant medications prior to urologic surgical procedures have arisen. If such medications can be temporarily discontinued perioperatively with minimal risk to the patient, it is reasonable to do so. However, URS can be safely performed if necessary while patients remain anticoagulated. Turna *et al*. retrospectively analyzed 37 patients undergoing flexible URS while on warfarin, clopidogrel or Aspirin, and compared them with a matched cohort of patients treated without anticoagulation [10]. No procedure had to be terminated due to poor visibility from bleeding and there was no significant difference in intraoperative or postoperative complications in the two groups.

All URS procedures should begin with surveillance of the bladder with particular attention paid to the location and configuration of the ureteral orifices. If the ureteral stone is readily visible at the expected location on initial fluoroscopic imaging, we generally do not perform a retrograde pyelogram initially since the injected contrast may obscure visualization of the stone. However, if the stone is not easily seen or there is a question regarding the ureteral anatomy, then it is best to perform a retrograde pyelogram to define the involved collecting system and ureter. The next step is passage of a wire past the stone and into the renal pelvis. A variety of guidewires are available, although we generally prefer a hydrophilic wire with a curved tip as this usually is the easiest to manipulate around the stone with minimal trauma to the ureter. Once the wire is confirmed to be in the renal pelvis, a second guidewire may be placed as a safety wire. In the less common situation in which a wire cannot be placed by the stone, the ureteroscope can be passed to the stone and then a wire can often be manipulated by the stone under direct visualization. If this is not possible, then careful fragmentation of the stone can be performed to free some space in the ureter alongside the stone and then the wire can be placed. If a semi-rigid instrument is to be used, this can often be placed alongside the initial wire without the need for a second wire. If a flexible ureteroscope is to be used, this is generally passed over a wire or through a ureteral access sheath. In this case, the wire is usually removed after the scope is in position, so it is best to initially place a second wire as well that can be maintained throughout the procedure as a safety wire.

When passing the semi-rigid ureteroscope, it is important never to try to advance the instrument if visualization is limited or there is significant resistance, even if going over a guidewire. In most cases, active dilation of the ureter is not needed as the instruments are small enough to pass. However, in the presence of a stricture or in selected other cases, active dilation using a balloon dilation catheter or progressive dilators can be considered. Irrigation by an assistant using a hand-held syringe or other pumping device is often helpful to improve visualization; however, it is important to use this judiciously to avoid displacement of the stone more proximally. Pressure pumps are also available, although we prefer to use a hand-held syringe, which allows better control of the force with which the irrigant is delivered. Similar issues exist for the flexible ureteroscope, which is almost always passed initially

over a wire to the level of the stone. As mentioned above, ureteral sheaths are available and are very helpful, particularly with flexible endoscopy, as they often facilitate passage of the instrument and allow for multiple insertions of the scope to remove fragments, etc. If difficulty is encountered in safely performing the procedure, it is always best to simply place a ureteral stent and allow for passive ureteral dilation, which generally makes a secondary URS procedure much easier to perform at a later date.

Stone fragmentation and removal (see Video 38.1)

Once the ureteroscope has been successfully advanced to the level of a ureteral stone, a decision needs to be made whether to try and remove it intact or fragment the calculus. In previous years, when larger instruments were routinely used and the ureter was frequently dilated with a balloon or by another method, it was more common to remove stones intact. However, the advent of smaller scopes that may be passed without active dilation has made it more difficult to directly extract larger stones without risking damage to the ureter. As a general rule, when in doubt about whether a stone can be successfully removed without fragmentation, it is best to err on the side of caution and break it into pieces prior to removal. The two most commonly used methods to fragment ureteral stones are laser lithotripsy and pneumatic lithotripsy. The holmium:YAG laser is used commonly and offers several advantages in stone fragmentation. First, it can be used to fragment all stones irrespective of composition or hardness using small diameter fibers. Second, the smaller fibers can be easily passed through flexible endoscopes with limited effect on the ability to provide irrigation to ensure adequate visualization. When working in the ureter, there is no significant concern about limitations in the ability to deflect the instrument as may occur when dealing with renal stones, particularly those in the lower calyces. Another advantage is the ability to ablate the stone, converting it to dust particles that do not have to be actively removed. The main disadvantage of the holmium:YAG laser is the associated cost of the instrument itself and of the disposable fibers.

Pneumatic lithotripsy most commonly involves the use of the Lithoclast device. This instrument is also highly effective in fragmenting stones and is generally associated with lower costs than those seen with the holmium:YAG laser as nondisposable probes are available. Disadvantages of pneumatic lithotripsy include the rigid probes which cannot be used with a flexible ureteroscope and the increased risk of retrograde stone propulsion. Mandal *et al*. compared laser and pneumatic lithotripsy for ureteral stones in a randomized, prospective study and found that both methods were safe and effective [11]. However, the immediate stone clearance rate was significantly better in the laser group and stone migration occurred in 16% of cases using the pneumatic device. Similar results when comparing laser and pneumatic lithotripsy in treating ureteral stones were reported by Maghsoudi *et al*. [12].

Once the stone has been adequately fragmented, or if it is to be removed intact, a variety of devices can be used for stone retrieval. Stone baskets are available in a variety of shapes and configurations and personal preference is probably most important in selecting which to use. In most cases, our preference is a tipless, nitinol basket when using the flexible instrument, and stone graspers with a rigid instrument. The advantage of the graspers is that the stone can be more easily disengaged if it is too large to remove and it will generally fall out of the graspers before significant damage to the ureter can occur. The baskets hold the stones more securely, but if the size of the calculus has been misjudged, it may be more difficult to disengage the stone from the basket for further fragmentation. In addition, the ureter can be damaged as the stone and basket are pulled distally if too much force is applied.

Another decision that needs to be made after the stone has been fragmented in the ureter is whether to try and remove all the fragments during the procedure or to allow them to pass later. It is generally our practice to remove all fragments from the ureter and this approach is supported by the results of a recently published study [13]. Schatloff *et al*. randomized 60 patients undergoing URS with laser lithotripsy to intraoperative fragment retrieval or spontaneous fragment expulsion. Although the results were somewhat clouded by variations in postoperative stent placement and the etiology of symptoms following the procedure, there was a significantly higher rate of unplanned medical visits in the group with incomplete fragment extraction. In addition, there was a trend towards higher rates of rehospitalization, residual stones, and the need for ancillary procedures in this group [13].

The role of postoperative stenting after URS stone removal is controversial and will be addressed in Chapter 46.

When performing URS stone removal, prevention of inadvertent retrograde calculus migration is important

in achieving a successful outcome. This is particularly true when using a semi-rigid instrument since it may not be possible to advance the scope further proximally in the ureter to reach the stone if it has been displaced. In some situations, a flexible ureteroscope may not be available and some surgeons may not be comfortable performing flexible endoscopy. A variety of approaches are available to help avoid stone retropulsion. First, when using the holmium:YAG laser to fragment the stone, we try to place the fiber on top of the stone rather than on the most distal portion, so that the energy delivered to the calculus is less likely to push it more proximally. Second, some semi-rigid instruments have two working channels which allow the stone to be engaged in a basket placed through one channel while the laser fiber or pneumatic probe is placed through the other channel. In addition, baskets that can accommodate a laser fiber to be placed through them are also available. Third, instillation of lidocaine jelly proximal to the stone appears to help prevent retropulsion [14]. Zehri *et al*. used a 5F ureteral catheter advanced beyond the stone to instill 2 mL of lidocaine jelly. Semi-rigid URS was then performed and the stones were fragmented using a pneumatic lithotripsy device. When comparing groups using lidocaine jelly and a randomized control group treated without, there was significantly less proximal stone migration and a better stone-free rate at 2 weeks in those receiving lidocaine [14]. Finally, a variety of antiretropulsion disposable devices are available [15–17]. In general, these devices are placed proximal to the stone and are then deployed in a configuration that prevents stone migration as fragmentation occurs. They may also help in removal of stone fragments as they are pulled distally after fragmentation is completed. Reduction in stone retropulsion using these devices has been demonstrated both *in vitro* and in clinical assessments [15–17]. The primary disadvantage of these antiretropulsion devices are the associated cost. Overall, when a flexible ureteroscope is available and the operating surgeon is comfortable and experienced with its use in the proximal ureter and kidney, stone migration is a minor concern and can usually be avoided with simple measures as described above. However, if semi-rigid URS is the only available option, then retropulsion is a greater concern since there is a risk that the procedure will not be completed successfully, leading to the need for secondary approaches, such as ESWL, if the stone moves into the proximal ureter or kidney before it is adequately fragmented. In such circumstances, extra efforts to avoid stone migration, such as the use of retropulsion devices, may be appropriate.

Complications

Advances in fiberoptic technology and the availability of smaller and flexible instruments have led to an overall improvement in the safety of URS stone removal. However, complications may still occur due to mucosal injury from the endoscope itself or from the use of lithotripters to fragment stones within the ureter. The most common complication is ureteral perforation or the development of a false passage in the ureter. In general, this should be easily recognized at the time of the occurrence or when a retrograde pyelogram is performed at the completion of the procedure. As long as a safety wire is left in place, minor perforations generally are easily managed by the placement of a ureteral stent which is left in place for up to 4–6 weeks depending upon the extent of the injury. There is an increased risk for the development of ureteral strictures after perforation has occurred, so imaging 6–12 weeks after the stent is removed is essential in these cases, even if the patient is asymptomatic [18]. If a stent cannot be placed or if the injury is more extensive, then a percutaneous nephrostomy tube may be placed.

Overall, the incidence of strictures following URS stone removal is 1–2% [18, 19]. In addition to ureteral injury, the extent and duration of stone impaction may increase the risk of stricture formation. Some authors have recommended routine imaging following stone removal since silent obstruction may occur. Weizer *et al*. reported that seven of 459 patients undergoing URS stone removal were asymptomatic despite the development of ureteral strictures [19]. Therefore, they recommended that all patients undergo imaging of the upper urinary tract within 3 months after stone removal. Adiyat *et al*. investigated the need for routine postoperative imaging in 253 patients undergoing URS stone removal [18]. While the overall incidence of stricture formation in this group was 1.4%, 0 of 158 patients with uncomplicated procedures developed strictures. Complicated patients were defined as those with ureteral perforation, stone impaction or the need for balloon dilation of the ureter. Therefore, these investigators concluded that routine follow-up imaging is not essential after uncomplicated URS.

The most serious complication of URS stone removal is ureteral avulsion, which fortunately is a rare occurrence. Ureteral avulsion most often results from trying to pull a stone that is too large to be removed intact down the ureter in a basket. The treatment of ureteral avulsion depends on the extent and location of the injury. If the distal ureter is the site of injury, avulsion can be managed by ureteral reimplantation with the use of a psoas hitch or Boari flap. For injuries that occur in the mid or proximal ureter, management can be quite challenging and may require ureteral substitution, autotransplantation of the kidney, or even nephrectomy. Surgery is best performed immediately to avoid the development of edema and inflammation, which can hamper a successful outcome. If a delay in treatment is necessary, then a nephrostomy tube should be placed.

Conclusions

URS stone removal has become the procedure of choice for most patients with ureteral stones. With modern fiberoptic technology, the availability of effective lithotripsy devices, such as the holmium:YAG laser and pneumatic devices, and flexible endoscopes, the success rate in removing ureteral stones at all levels of the ureter is excellent. Issues related to stone migration can be effectively managed using a variety of techniques and disposable devices that are readily available, allowing for a minimal risk of the need for secondary procedures to remove stones. Overall, URS stone removal is highly effective, with a low risk of complications, and it can be performed successfully and safely by most urologists.

CHAPTER 39
Ureteroscopic Management of Renal Calculi

Sven Lahme
Department of Urology, Siloah St Trudpert Hospital, Pforzheim, Germany

Introduction

During the last three decades treatment modalities for renal calculi have undergone several significant changes. Prior to the introduction of extracorporal shock-wave lithotripsy (ESWL), open surgical removal of stones from the upper urinary tract was the treatment of choice. In the 1980s ESWL was introduced and open surgical treatment of renal calculi was only performed in patients with large stone burden. As ESWL only fragments renal stones, stone passage via the ureter is necessary. Although ESWL is a treatment modality with low morbidity, the stone-free rates are disappointing; only up to 50% even for lower pole stones. This led to the invention of percutaneous stone removal. By means of conventional nephroscopes, renal calculi can be removed with a percutaneous approach to the kidney. Percutaneous nephrolithotomy (PCNL) offers a significant increase in stone-free rate, but the morbidity with PCNL is significantly higher than with ESWL. This dilemma could be solved by using a retrograde access to the renal calyceal system.

In the 1990s, flexible endoscopes became available and these could reach the upper urinary tract. However, these instruments were disadvantaged by their diameter, initially between 9F and 13F, and the limited ability to deflect the tip of the instrument. Also, no disposables were available to facilitate the access to the ureter. In the late 1990s the development of new flexible ureteroscopes began. There was a significant improvement in the deflection angle, which now reaches 270° [1, 2]. Another important improvement was the decrease in diameter to 7.5–9F. Simultaneously, ureteral access sheaths became available, allowing easy access to the ureter. Special baskets and stone retrieval systems, such as tipless baskets and “Graspit,” were invented. Another very important step in the introduction of endoscopic treatment of renal calculi was the introduction of holmium laser systems. Due to the limited diameter of the working channel, ultrasound probes and ballistic lithotripsy were almost impossible to use. Only laser lithotripsy allowed the treatment of all upper urinary tract calculi. Due to the small caliber of the laser fibers, deflection of the flexible endoscopes is not significantly reduced.

Today there is a great variety of flexible ureterorenoscopes from different companies. These allow almost all parts of the calyceal system to be entered. In combination with particular disposables that facilitate the access to the upper urinary tract, flexible ureterorenoscopy (URS) has become an essential part of the treatment of renal calculi. Due to the low morbidity of flexible endoscopic treatment of renal calculi and the enhanced stone-free rate in comparison to ESWL, it is expected that primary endoscopic treatment of renal calculi will probably become the treatment of choice (Figure 39.1).

Indications

The different treatment modalities open to patients suffering from upper urinary tract calculi are: ESWL, retro-

grade flexible URS, conventional PCNL, miniaturized PCNL (mini-perc), and open surgical and laparoscopic removal. The decision as to which treatment modality should be recommended is dependent on several stone characteristics (size, locaation, composition, if available), as well as morphology of the urinary tract, complication rate, patient preference, available technical equipment, and economic aspects (Table 39.1).

If it is intended to treat renal calculi by means of flexible URS, it should be remembered that all fragments of the renal stone have to be taken out via the ureteral access sheath. Increasing stone size is associated with increasing operating time and increasing risk of pyelonephritis. Only a limited number of reports in the literature describe the indications for endoscopic management of renal calculi. The guidelines of the European Association of Urology (http://www.uroweb.org/?id=218&gid=13)

recommend flexible URS only as a third-line therapy in patients suffering from renal stones with a diameter less than 2 cm. In stones that exceed a diameter of 2 cm, flexible ureterorenscopy is not recommended (Table 39.2). The joint European Association of Urology and American Urological Association Urolithiasis Guidelines Panel has recommended treatment of ureteral stones by means of an endoscopic approach, but flexible ureterorensocopy as a primary approach to upper urinary tract calculi has so far not been recommended. The German Association of Urology recommends flexible URS in stones with a diameter up to 1 cm as a second-line therapy and in stones with a diameter from 1 to 2 cm as a third-line therapy (Figure 39.2).

Table 39.3 Results of flexible ureterorenoscopy in upper urinary tract calculi in a high-volume center (n = 802).

Mean stone size (mm^2)	57.5
Adjuvant shockwave lithotripsy (%)	23.9
Holmium laser lithotripsy (%)	46.6
Mean operating time (min)	49.6
Stone-free rate (%)	86.3
Retreatment rate (%)	11.5
Pyelonephritis (%)	9.8
Perforation (with complete convalescence after double-J stenting) (%)	1.7
Major complications (%)	0.0

Table 39.4 Indications for retrograde flexible ureterorenoscopy in renal calculi.

Proximal ureteral stones, if rigid ureteroscopy is not possible or suitable
Residual renal pelvic and calyceal stones after shock-wave lithotripsy, rigid ureteroscopy or percutaneous procedures
Diverticular stones (incision of the neck of the diverticulum and removal of the stone)
Primary treatment of renal pelvic and calyceal stones on an individual basis

Thus, there is only a second-line indication for flexible URS in the treatment of upper urinary tract calculi. Therefore, the decision to use flexible URS as the primary approach in patients with upper urinary tract calculi must be made on an individual basis. Surgeons should inform patients about possible side effects, stone-free rates, and the fact that flexible URS is as yet not recommended in guidelines. Also, no large randomized trials concerning flexible URS have been reported so far The experience with flexible URS in the treatment of renal stones as a primary approach mainly comes from single-center studies(Table 39.3).

A summary of the current accepted indications for retrograde flexible URS is given in Table 39.4.

Access to the upper urinary tract

In contrast to rigid URS, flexible scopes cannot usually pass the ureteral orifice without additional help, due to the ability to deflect the tip of the instrument and the configuration of the tip.. There are two main possibilities to solve this problem: (1) insert a guidewire into the ureter and pass the flexible scope over the guidewire, and (2) make use of a ureteral access sheath.

Guidewires

With the use of a guidewire it is very easy to reach the ureter and the upper urinary tract. However, there are disadvantages with this method. There is a risk of altering the ureteral orifice as the tip of the flexible instrument may be sharp. Once the instrument is inserted, irrigant cannot flow back to the bladder, and the limited irrigation may restrict the endoscopic view. Another consequence is the increased risk of febrile urinary tract infections due to an enhanced irrigation pressure inside the ureter and calyceal system. If the treatment of stones requires several passages of the ureter in order to remove the fragments, the approach to the ureter will be lost if the guidewire was inserted for this purpose and no access sheath had been used. In this case the use of a guidewire is time consuming. In addition, the sharp edges of stone fragments, which are taken out through the ureter, may alter the ureteral wall, and cause bleeding and a poor endoscopic view.

Ureteral access sheaths

Ureteral access sheaths are easy to use in the approach to the ureter. Access sheaths with different diameters are available from different companies. First a guidewire is inserted under X-ray control, and then the access sheath is inserted over the guidewire. The access sheath itself consists of two parts: the inner part with a tip to dilate the ureteral orifice, and an outer part made from an enforced material to avoid any buckling. The size of the ureteral access sheath chosen will depend on the particular situation of the patient. If the ureter has a double-J stent or the patient is female, a 14/16F ureteral access sheath is recommended. The decision as to which ureteral access sheath to use should be taken with care and should consider the morphology of the ureter.

Another important consideration is the stone burden to be treated. The larger the stone burden and thus the greater the number of stone fragments to be expected, the larger the ureteral access sheath should be. The ureteral access sheath allows easy re-entry of the calyceal system and multiple passages for removal of stone fragments, which is a significant advantage over the use of a guidewire in flexible URS.

Another advantage that should be mentioned is the fact that the pressure of irrigant in the calyceal system is low, due to the space between the flexible scope and the inner wall of the access sheath. Febrile infections, which may be caused by an enhanced pressure, occur very rarely when ureteral access sheaths are used in the treatment of renal calculi [3].

Ureteral access sheaths were previously suspected of causing ureteral alterations such as strictures. However,

there is evidence that their use does not increase the rate of ureteral strictures [4].

In summary, access to the upper urinary tract by means of ureteral access sheaths is quite easy and safe if the size of sheath is chosen according to the morphology of the urinary tract, stone size, and number of expected stone fragments to be removed. They are a necessary auxiliary tool in the treatment of renal calculi [5–7].

Lithotripsy in flexible ureterorensocopy

Intracorporeal lithotripsy plays an important role in flexible URS. As all stone fragments have to be taken out through the ureteral access sheath, the aim of lithotripsy is to produce fragments of a size that can be withdrawn through its inner cross-section. The more successful lithotripsy is at this, the faster the patient will become stone free.

There are different lithotripsy devices available: ballistic lithotripsy, ultrasound lithotripsy, electrohydraulic lithotripsy, and laser lithotripsy. Their most important aspect is that they should not influence the ability to deflect the tip of the instrument. Ballistic lithotripsy does not play an important role in flexible URS as its flexible probe decreases significantly the deflection angle of the tip of the flexible scope [8]. As there are no flexible probes available for ultrasound lithotripsy, it also is not suitable for flexible URS. In principle, electrohydraulic lithotripsy is possible in flexible URS, but due to the difficulty controlling the energy applied to the stone, it cannot be recommended in flexible lithotripsy.

The lithotripsy device of choice in flexible URS is a laser. Two different kinds of laser suitable for the treatment of renal calculi are available: the holmium:YAG and neodymium:YAG lasers. Both employ deflectable laser fibers. Their main difference is that the holmium laser can fragment all types of stone, whereas the neodymium:YAG laser does not fragment cystine stones. The size of stone fragments can be defined during lithotripsy by an experienced endourologist [9].

In summary, the lithotripsy device of choice is the holmium laser. Using small-caliber probes, the deflection of the tip of the flexible scope is not noticeably decreased.

Stone retrieval systems

In the age of rigid ureteroscopy, reusable forceps were the device of choice to remove stones. Due to the limited diameter of flexibles scopes, new stone retrieval devices have been invented. The diameter of modern small-caliber devices is about 1.1F, 1.3F or 1.5F, which allows maximum irrigation flow and maximum deflection of the tip of the instrument, i.e. almost all parts of the calyceal system can be reached by means of these modern devices. The combination of flexible scopes and minimally invasive flexible stone retrieval devices gives a high stone-free rate after flexible URS.

In contrast to the Dormia baskets used in the ureter, tipless baskets are used in the renal calyceal system to "catch" calyceal stones located at the calyceal wall. As there is no overlaying tip, which may cause bleeding at the calyceal wall, tipless baskets provide a clear view [10]. Recently these tipless baskets have been modified to further facilitate the catching of stones (Figure 39.3). Single-use graspers or forceps are also available, but in practice these forceps are not as reliable in catching stones as the tipless baskets.

Given the cross-section of the retrieval device, a decrease of irrigant flow and deflection angle has to be accepted [11].

Definition of "stone free"

In order to compare the effectiveness of modern endourologic treatment modalities with earlier results for ESWL, it is important first to define what is meant by the term "stone free." In ESWL studies, a patient was considered to be stone free if the diameter of residual fragments did not exceed 4 mm. Whether there are residual fragments or not can be determined by X-ray [kidneys, ureter, and bladder (KUB)]; computed tomography (CT) scan or ultrasound examination, but all these methods are limited by inter- and intra-observer variation. Also, not all radio-opaque findings on X-ray examination correspond to intraluminal stones. A study of 400 flexible URSs showed that 12% of all calcifications detected by means of X-ray examination were parenchymal calcifications, which do not need to be treated (Figure 39.4). If endourologic treatment modalities are used, stone-free status is determined under direct endoscopic vision. If flexible URS or percutaneous techniques are performed, there should be no residual fragments. Thus the results of ESWL cannot easily compared to the results of endoscopic procedures, and the greater stone-free rate achieved with flexible URS compared with ESWL is probably an underestimate.

Treatment

Small stone burden

Renal stones with a diameter of less than 1 cm can easily be treated by retrograde flexible URS (see Video 39.1). As mentioned above, the diameter of the access sheath should be chosen according to the size of the stone, morphology of the urinary tract, and expected stone composition. Unfavorable stone localizations, such as in lower poles, can be managed by the relocation of the stone to the renal pelvis. In this position the stone can easily be fragmented and all fragments can be removed.

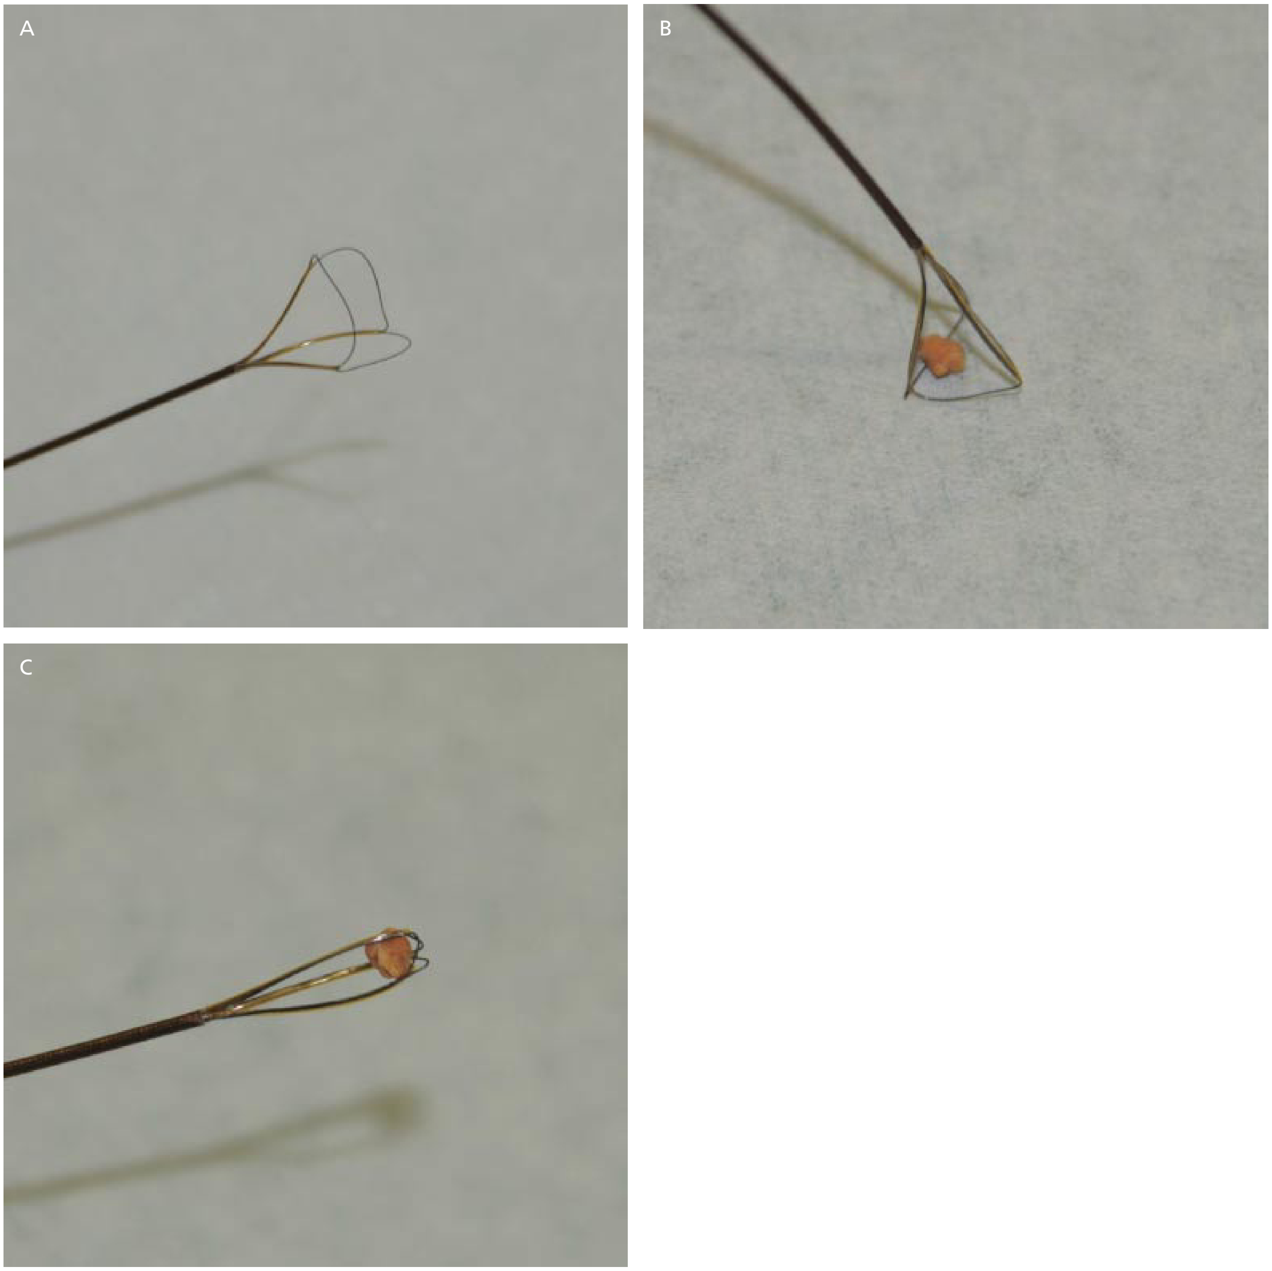

Figure 39.3 Special nitinol devices facilitate the removal of calyceal stones. (A) Opened basket (N-Gage, Cook Urological, Bloomington, IN, USA). (B) Basket positioned to catch the stone. (C) Basket with caught stone.

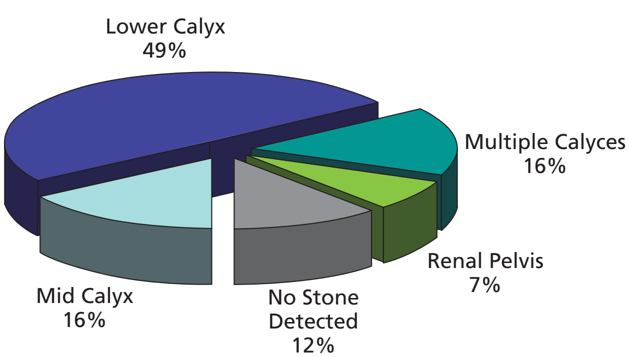

Figure 39.4 Distribution of stones in upper urinary tract calculi (n = 400).

Stones that are too large to be accommodated by the inner diameter of the ureteral access sheath can sometimes be extracted by simultaneous removal of the access sheath. In this case, a guidewire should be inserted prior to removal of the ureteral access sheath in order to retain access and keep the operating time as short as possible.

The edges of fragments of calcium oxalate monohydrate stones are often sharp, which makes it more difficult to remove them via the access sheath, Therefore, these stones should be fragmented completely. Infection

stones often fragment while being pulled through the access sheath. If all visible fragments have apparently been removed from the calyceal system, a final evaluation of the calyceal system is recommended. It is advisable first to look for stone fragments in the upper pole, then in the mid calyx, and lastly in the lower pole. The latter is important because flexible endoscopy of upper urinary tract stone fragments often leads to their migration from the upper to the lower calyx [12].

The aim of endourologic treatment of renal stones is to achieve endoscopically confirmed stone-free status (Figure 39.5).

Large stone burden

Stones exceeding a diameter of 2 cm are difficult to treat. Due to the limited diameter of the ureteral access sheath, the number of stone fragments to be removed will increase with large stones, and a significant increase in operating time has to be accepted. A study by Ober *et al*. compared flexible URS in large stones (>100 mm^2) to a control group with smaller stones (<100 mm^2). The operating times were 70 min and 47min, respectively, but stone-free rates were comparable (84.3% and 91.7%, respectively). The main differences were in the retreatment rate (47% and 12%, respectively) and risk for febrile urinary tract infection (17.6% and 4.2%, respectively) (Table 39.5). To evaluate these results, treatment alternatives, such as a minimally invasive PCNL (mini-perc), should also be taken into consideration (Table 39.6).

Diverticular stones

A particular difficulty is the treatment of diverticular stones [13]. The morphologic obstruction caused by the neck of the diverticulum should be treated at the same time in order to prevent stone recurrence (Figure 39.6). If flexible URS is used to treat diverticular stones, it is proposed that the diverticular neck is treated first. In contrast to percutaneous approaches, this has to be done using a holmium laser as otherwise it will not be possible to reach and remove the diverticular stone.

The success of retrograde flexible URS in the treatment of diverticular stones depends on their location in the diverticulum. Unfortunately, a standard intravenous pyelogram (IVP) only shows a two-dimensional aspect of the diverticulum. In practice diverticular stones often are located in a dorsal or ventral calyx, which means that the flexible scope has to manage two deflections in two different directions. This can explain why sometimes the retrograde flexible approach does not reach the diverticular stone.

ESWL does not represent an alternative treatment because, while it will fragment diverticular stones, it has no impact on the morphologic obstruction. The main treatment alternative in the treatment of diverticular stones is a percutaneous approach by means of PCNL. Aguilar *et al*. compared three different treatment modalities in diverticular stones: flexible URS, mini-perc, and a combined approach (Table 39.6), and found success rates of 66.7%, 94.1%, and 77.8%, respectively. Flexible URS is effective in upper pole diverticular stones, whereas mini-perc is more successful in lower pole diverticular stones.

In summary, retrograde flexible URS offers an effective treatment modality in diverticular stones compared to ESWL, but a percutaneous approach to diverticular stones is the most effective treatment modality. Flexible URS has some limitations, , particularly in lower pole diverticular stones [14].

Renal stones in children

Although retrograde endoscopy in children is very common for ureteral stones, there is only limited experience in the primary retrograde treatment of renal stones. To date ESWL is the treatment of choice for calyceal stones in children. However, due to the ability of the infant ureter to pass large stones spontaneously, it is questionable if a primary retrograde approach to renal stones is necessary. In contrast to the limited data for retrograde flexible procedures in children, there is evidence that a percutaneous approach in children with large stone burden is as effective and secure as in adolescence. The future will show if the ongoing miniaturization of flexible scopes will lead to a more significant role for retrograde flexible ureteroscopy in children.

Management of complications

Although flexible URS is easy to learn, there are a few complications that should need to be managed during the procedure. Most of these difficulties have not been reported in the literature and no statistical data for their incidence are available. The main complications with flexible URS are discussed below, together with tips for overcoming them.

Inability to insert a ureteral access sheath

In about 15–20% of all patients scheduled for retrograde flexible URS to treat upper urinary tract calculi, a primary approach to the upper urinary tract by insertion of a ureteral access sheath is not possible. Usually this is not due to a stricture or other pathology of the ureteral orifice. Instead, a muscular spasm of the wall of the ureter inhibits the placement of the ureteral access sheath. Sometimes it is suitable first to dilate the ureter using the inner part of the ureteral access sheath. If this does not work, a double-J stent should be placed and the planned procedure delayed for 3 or 4 days.

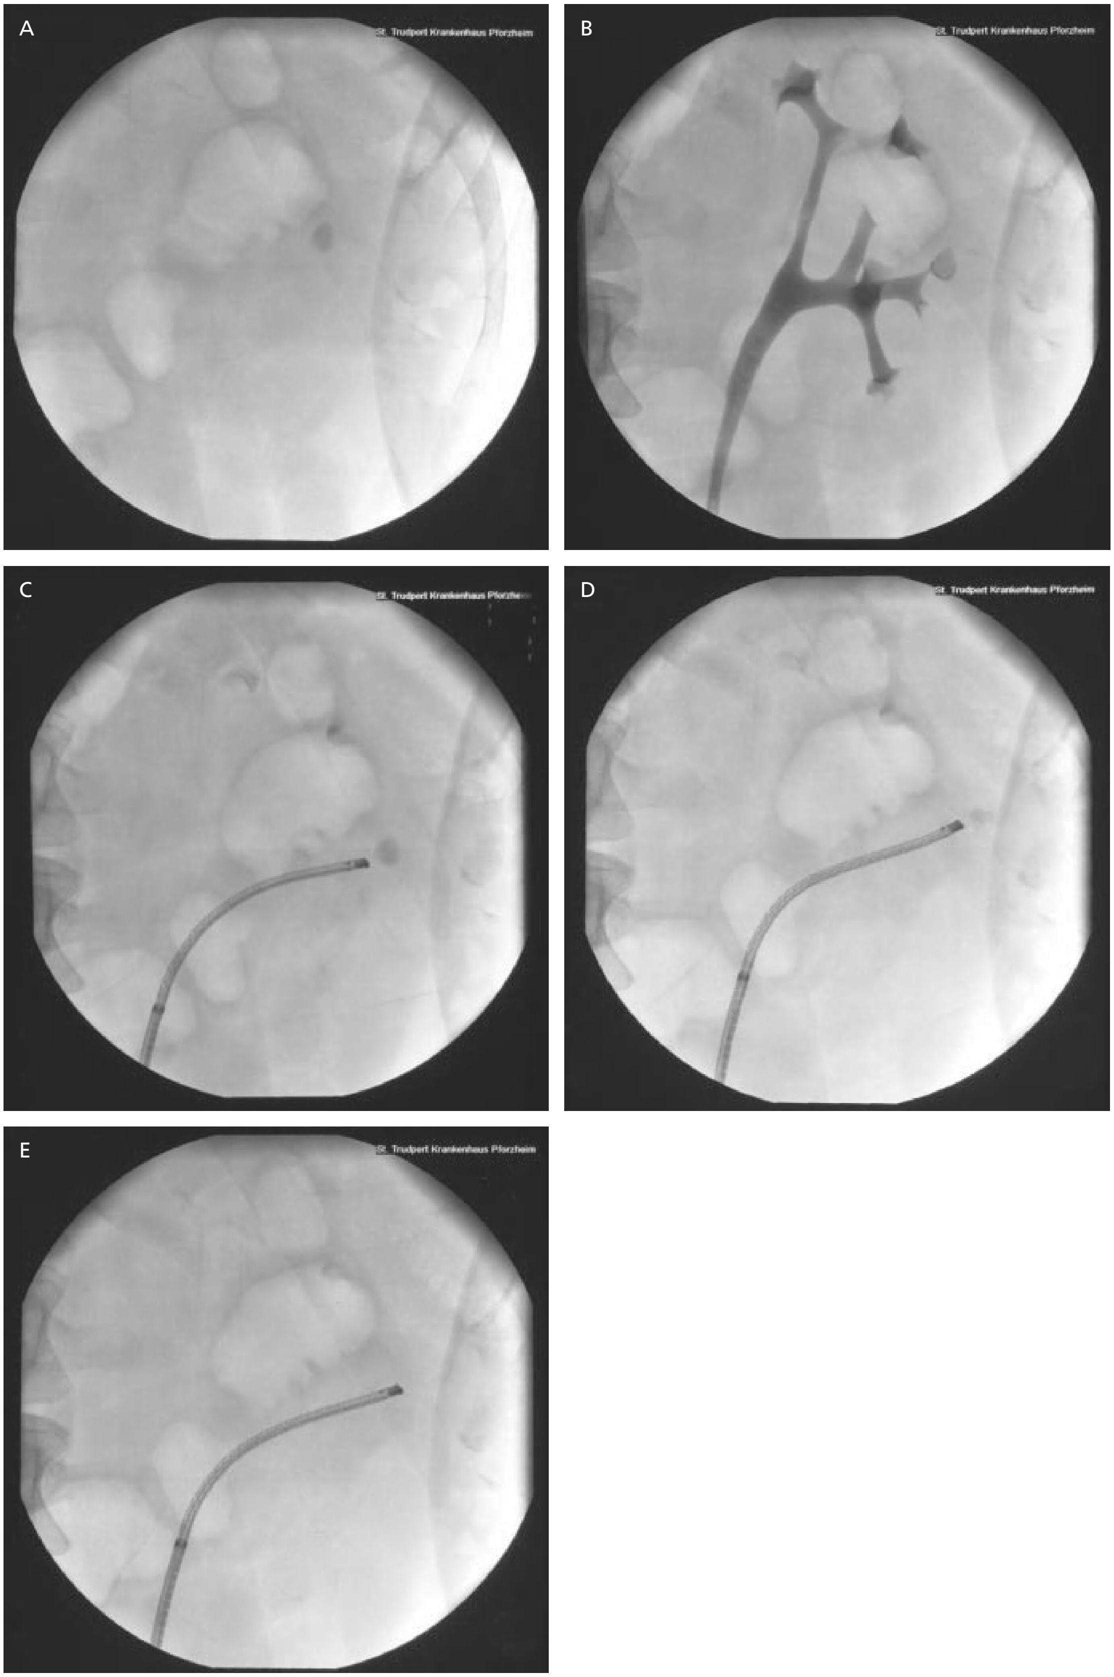

Figure 39.5 Treatment of a mid calyceal stone by means of retrograde flexible ureterorenoscopy. (A) Radio-opaque stone of the mid calyx with a diameter of 10 mm. (B) Retrograde pyelography of the calyceal system. (C) Flexible scope facing the mid calyceal stone. (D) Fragmented stone after holmium laser lithotripsy. (E) Complete removal of the mid calyceal stone.

Perforation of the ureter

Perforation of the ureter can occur if the ureteral access sheath is placed too forcefully. Another possibility is that the ureteral access sheath was moved forward after the inner part of the access sheath had been removed. Infrequently the cause of the perforation is the flexible scope itself. In case of perforation, it is recommended that a double-J stent and a transurethral catheter are inserted. By creating a low pressure urinary diversion, these perforations will recover without any long-term complications. The main advice to prevent ureteral perforations is to perform the procedure with care and not to force any step of the procedure.

Unfavorable stone position

Sometimes stones are located in unfavorable locations, such as the diverticula, lower poles or calyces with ventral or dorsal position. In all these cases it is recommended first to move the stone to a more favorable position and then to perform fragmentation. The best stone position for further treatment depends on the anatomy of the calyceal system. In many cases, stones should be moved to the mid calyx. If lithotripsy has been started, it is very important to avoid any migration of stone fragments to other parts of the calyceal system, as catching these fragments is very time-consuming and the stone-free rate may be reduced [15–17].

Table 39.5 Results of ureterorenoscopic management in renal calculi with large stone burden in comparison to smaller stone burden.

	Stone burden < 100 mm^2	Stone burden > 100 mm^2
Number	393	127
Operating time (min)	47	70
Stone-free rate (%)	91.7	84.8
Retreatment rate (%)	12.0	47.0
Pyelonephritis (%)	4.2	17.6
Perforation (%)	2.5	3.2

Respiratory movement of the kidney

There is significant movement of the kidney with the patient's breathing. In small calyceal stones and narrow renal pelvices particularly, it is recommended that this respiratory movement of the kidney is reduced in collaboration with the anesthesiologist, who can stop the respiration for several minutes in order to facilitate stone removal. This collaboration illustrates how the maximum success in endourology can only be achieved with a team consisting of surgeon, nurse, and anesthesiologist.

Impacted stone inside a tipless basket

A calyceal stone that has been successfully caught may be too large to be extracted, but cannot be removed from the tipless basket. In these cases a holmium laser can be used to cut one of the wires of the tipless basket. In future new hand grips will be available to disconnect and reconnect the tipless basket.

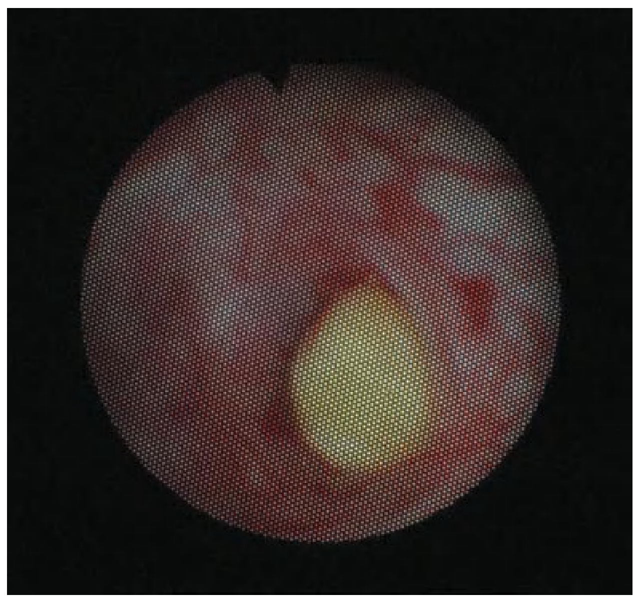

Figure 39.6 Endoscopic view of a diverticular stone. The diverticular neck has not been incised and only the distal tip of the stone is visible.

Table 39.6 Results of ureterorenoscopic management of renal diverticular stones in comparison to mini-perc and combined approach.

Group	Total number	Upper pole diverticulum (n)	Mid calyx diverticulum (n)	Lower pole diverticulum (n)	Stone-free rate (%)
Flexible ureterorenoscopy	6	4	0	2	66.7
Mini-perc	17	1	5	7	94.1
Combined approach	9	4	3	1	77.8

Breakage of laser fibers

There are only rare reports in the literature dealing with the management of broken laser fibers, but all experienced endourologic surgeons know about this problem. As lost fragments of the laser fiber can cause stone recurrence, it is recommended that these fragments are caught immediately using disposable forceps, such as the "Graspit." Tipless baskets are not effective as they will catch the laser fiber fragment across the tipless basket.

Adjuvant shock-wave lithotripsy

Sometimes it is advisable to combine ESWL with retrograde flexible URS. The few studies that have evaluated this approach suggest it is beneficial for large peripheral stone burden that cannot easily be reached by retrograde flexible URS alone [18, 19]. After fragmentation of the calyceal stone, smaller fragments can be removed by means of flexible URS in a second session. This combination treatment may be one of the most important indications for ESWL in the future [18, 19].

Treatment alternatives to flexible ureterorenoscopy

The effectiveness of flexible URS can only be evaluated if compared to other treatment alternatives. From the endourologic standpoint, mini-perc is the main treatment alternative to retrograde flexible URS. A short overview of the differences between these treatments is given below (Table 39.7).

Access to upper urinary tract

Flexible URS is an easy to perform if suitable disposables, such as ureteral access sheaths, are used. Even for beginners with no particular endourogic expertise, the insertion of a ureteral access sheath and the approach to the upper urinary can be learned quickly. In contrast, percutaneous techniques require a long learning curve.

Stone-free rate

Flexible scopes offer an enhanced stone-free rate in renal calculi in comparison to ESWL, but in comparison to percutaneous procedures, flexible URS gives a lower stone-free rate. Therefore, the decision about the endourologic procedure should be based on localization and size of stone. Solitary small stones in the upper or mid calyx in particular are very suitable for retrograde flexible URS. Stones in the lower calyx, particularly larger stones, are more suitable for a primary percutaneous approach [20, 21].

Table 39.7 Comparison of the main characteristics of retrograde flexible ureterorenoscopy to minimally invasive percutaneous nephrolithotomy in the treatment of renal calculi.

	Flexible ureterorenoscopy	Percutaneous approach (PCNL)
Approach	Easy to perform, if access sheath is used	Requires experience
Stone-free rate	High	Higher
Lithotripsy	Holmium laser	Holmium laser Ballistic lithotripsy Ultrasound lithotripsy
Treatment if hemostasis is altered	Decision on an individual basis possible	Impossible
Best stone localization	Upper calyx Mid calyx	Lower calyx
Best stone size	<2 cm	>2 cm
Costs	High	Moderate

PCNL, percutaneous nephrolithotomy.

Lithotripsy

Holmium laser lithotripsy is required with retrograde flexible URS. The small caliber of the working channel requires small laser probes. Ultrasound or ballistic lithotripsy are not possible in flexible URS. If percutaneous techniques are performed, holmium laser, ballistic, and ultrasound probes for stone fragmentation can be used. As ultrasound and ballistic lithotripsy are more cost-effective methods, a percutaneous approach is associated with lower costs compared to flexible URS.

Hemostasis

Flexible URS can be performed in patients with mild alteration of hemostasis, such as those on warfarin and Aspirin, although the decision to treat must be made on an individual basis. Percutaneous procedures in such patients are contraindicated [22, 23].

Technical equipment

When comparing flexible ureterenoscopy to percutaneous techniques, it is important to remember that the former is a high cost procedure because flexible scopes for the upper urinary tract are expensive to pur-

chase and repair. They are fragile and in inexperienced hands may be damaged easily. Percutaneous scopes are cheaper and more robust. The maintenance and sterilization process for flexible scopes is complicated due to their length and fragility, whereas rigid percutaneous scopes can easily be maintained and sterilized.

Limitations due to the morphology of the calyceal system

There are certain limitations to flexible URS in the upper urinary tract. Sometimes a long calyceal neck makes it impossible to enter a calyx, particularly lower calyces, and in these cases a percutaneous approach is more successful. Flexible retrograde and percutaneous approaches complement each other in these cases, and only the availability of both these techniques will offer the maximum success in endourologic treatment of renal calculi. Whether double-bending flexible ureterorenoscopes can play an important role in reaching outlying parts of the calyceal system is questionable [24–26].

Cost of treatment

One of the most important ongoing discussions in retrograde flexible URS concerns cost. As mentioned above, flexible scopes are very complicated and fragile instruments, and the deflection mechanism is easily damaged. The sterilization process is also very complex, due to the length of the flexible scope and the small caliber of the working channel. The distal tip of the working channel, manufactured from a plastic material that allows deflection of the instrument, is susceptible to alterations, which cause additional repair costs.

The durability of flexible scopes depends on the experience of the surgeon and staff involved in the sterilization process. In experienced hands the durability of a flexible scope is up to 50 procedures, in inexperienced hands only 5–10 procedures. In a study of 630 interventions using flexible scopes, the mean durability was 21 interventions. The average repair cost per procedure in 2009 was about €155 (c. US$215).

Flexible ureterenoscopy also carries additional costs due to the use of disposables, guidewires, ureteral access sheaths, tipless baskets, and ureteral stents.

Against these higher costs in comparison to other treatment alternatives, such as ESWL, the reduced treatment time for flexible URS should be considered. The reduced cost associated with this will vary from country to country, and also depend on national reimbursement systems. As such the cost-effectiveness of flexible URS will depend on the country in which a surgeon is practicing [27–30].

Antegrade flexible ureterorensocopy

So far only retrograde flexible URS had been discussed. In cases, where an additional percutaneous approach to the kidney is necessary, flexible scopes can be used to perform antegrade flexible ureteroscopy. By combining minimally invasive percutaneous procedures with antegrade and retrograde flexible ureteroscopies, almost all parts of the urinary tract can be reached. In order to achieve maximum success with flexible URS, antegrade access to the ureter should be considered. With an antegrade approach, a ureteral access sheath can be placed via a guidewire using the percutaneous access. Antegrade flexible URS is as easy to perform as the retrograde version, even in children [31].

Flexible ureterorenoscopy in anomalous kidneys (see also Chapters 61 and 62)

ESWL and percutaneous procedures are associated with particular difficulties in patients with anomalous kidneys with stones. Stone clearance after ESWL is poor and percutaneous access to the kidney is sometimes impossible. By means of retrograde flexible URS, renal calyceal stones can often be removed more easily. However, there have been only limited reported cases of this technique in anomalous kidneys [32].

Conclusions

URS management of renal calculi is a highly effective, reliable, and safe treatment modality, which should be offered to stone patients as a treatment alternative to ESWL. However, as flexible URS as a primary approach to renal calculi is not included among the general recommendations in international guidelines, it should only be performed with the explicit consent of patients. Using ureteral access sheaths and once sufficient experience in flexible URS has been acquired, renal calculi can easily be treated endoscopically. Retrograde flexible URS is not suitable if renal stones exceed 2 cm in diameter. In these cases a percutaneous approach by mini-perc is preferred from an endourologic point of view [33].

CHAPTER 40

Diagnostic Ureteroscopy

Michael J. Conlin

Dotter Institute of Interventional Radiology, Oregon Health & Science University, Portland, OR, USA

Introduction

Perhaps nowhere else have the improvements in ureteroscopic instrumentation had such a significant effect on treating patients than in diagnostic ureteroscopy. In the past, urologists were at the mercy of radiologic imaging capabilities to evaluate the upper urinary tracts of our patients. Computed tomography, angiography, and retrograde studies were the only tools available for evaluating patients with possible upper urinary tract abnormalities. With the development of safe and effective ureteroscopy, urologists need no longer rely on these radiologic imaging studies alone. Ureteroscopy has allowed us to better determine the underlying cause of bleeding in patients with benign essential hematuria, and has greatly improved our ability to treat these patients.

The first ureteroscopes to be developed were limited to diagnostic use because they lacked a working channel. These prototypical ureteroscopes had only visual and illuminating capabilities [1, 2]. As ureteroscopes rapidly improved with the development of working channels and deflection capabilities, their therapeutic role in treating upper urinary tract abnormalities, particularly urolithiasis, expanded greatly. Although these therapeutic indications dominate the use of ureteroscopes, the addition of working channels and deflection also improved their diagnostic capabilities. It is now possible to completely inspect the intrarenal collecting system, and through the working channel sample fluid for cytology and pass biopsy forceps to sample any abnormal tissue identified. The use of ureteroscopy as a diagnostic tool will grow as ureteroscopes continue to improve their imaging abilities, maneuverability, and durability. The diameter of ureteroscopes has decreased over the years of development, which greatly increases our ability to perform ureteroscopy without prior ureteral dilation, allowing clearer inspection of the untouched ureteral urothelium [3]. As the invasiveness of ureteroscopy decreases, there will be little reason to rely on radiologic studies alone when the urothelium of the upper urinary tract can be safely inspected and sampled.

This chapter will discuss the diagnostic uses of ureteroscopy, the specific technical nuances of diagnostic ureteroscopy, and current results of ureteroscopy for evaluating hematuria.

Indications

Ureteroscopy can be used diagnostically to investigate any condition that may involve the upper urinary tract. Ureteroscopy allows urologists direct visualization, fluid sampling, and tissue sampling of the upper urinary tract. Any evaluation for conditions that might benefit from these diagnostic interventions should be considered for ureteroscopy. Common indications for diagnostic ureteroscopy include evaluating patients with unexplained recurrent or persistent urinary tract infections, persistent positive cytologies, upper urinary tract filling defects, and hematuria [4, 5]. Ureteroscopic evaluation of filling defects and hematuria are discussed below.

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Figure 40.1 Small filling defect, ureteropelvic junction.

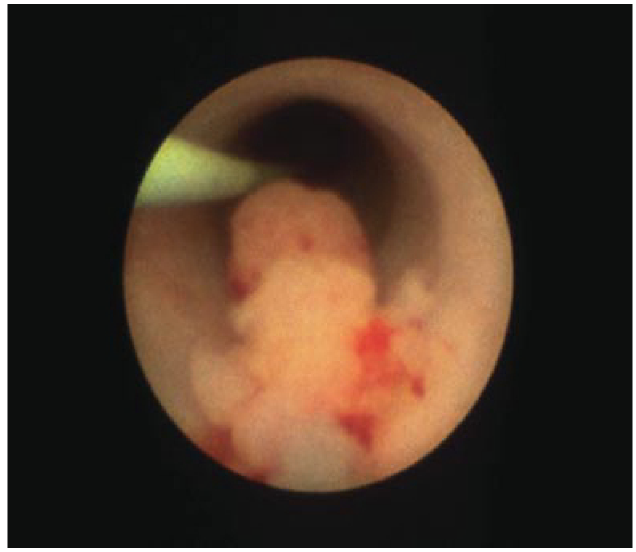

Figure 40.2 Papillary, low-grade tumor.

Upper urinary tract filling defects

Excretory urography is the most common imaging modality for evaluating patients with hematuria. Other upper urinary tract imaging studies evaluating patients with hematuria include renal sonography and computed tomography (CT) urography. Expanded use of CT urography with its ability to better identify radiolucent stones and better define soft tissue defects has decreased but not eliminated the need for diagnostic ureteroscopy evaluating filling defects. Despite improvements in upper urinary tract imaging for patients with hematuria, the evaluation of the upper urinary tract filling defects identified on imaging studies remains one of the most common indications for diagnostic ureteroscopy.

Filling defects may include calculi, transitional cell carcinoma (TCC), blood clots, benign tumor (e.g. fibroepithelial polyps), extrinsic compression (e.g. crossing vessels), and intrinsic ureteral strictures or ureteropelvic junction (UPJ) obstructions (Figure 40.1) [4].

Direct ureteroscopic inspection alone often provides the diagnosis when evaluating upper urinary tract filling defects [4]. Upper urinary tract calculi are easily distinguishable from soft tissue lesions, and treatment can be rendered using a holmium laser in the same setting. Extrinsic filling defects can often be determined visually with the appearance of compression of the ureter in the absence of any intrinsic mass in the ureteral lumen. When the ureter is extrinsically compressed by a venous structure, the ureteral lumen is distensible during ureteroscopic inspection, whereas extrinsic compression from an artery often results in visible pulsations. Ureteral strictures and UPJ obstructions also may be visually confirmed.

With the expanded use of CT urography, most upper urinary tract calculi can be identified before ureteroscopy. In this setting, most filling defects will be soft tissue in nature and should be considered cancer until proven otherwise. The ureteroscopic appearance of upper tract TCC is similar to the more familiar cystoscopic appearance of bladder-based TCC. Low-grade urothelial tumors have a typical papillary, frondular appearance (Figure 40.2). Higher grade tumors can be more sessile and at times appear necrotic (Figure 40.3). Fibroepithelial polyps, while often long and papillary, can be distinguished from upper urinary tract TCC as they frequently have a smooth, normal-appearing urothelial surface.

Although upper urinary tract TCC can often be determined by direct ureteroscopic inspection alone, this should not be the sole basis of its diagnosis. When evaluating any soft tissue lesion with concern for possible urothelial cancer, the diagnosis should be based on visual appearance, cytologic evaluation, and biopsy [6].

Treatment of upper urinary tract TCC depends on the location, size, and number of lesions. The most critical factors in deciding the course of treatment are the stage and grade of the tumor. Accurate staging of upper urinary tract TCC can be difficult. CT scanning alone

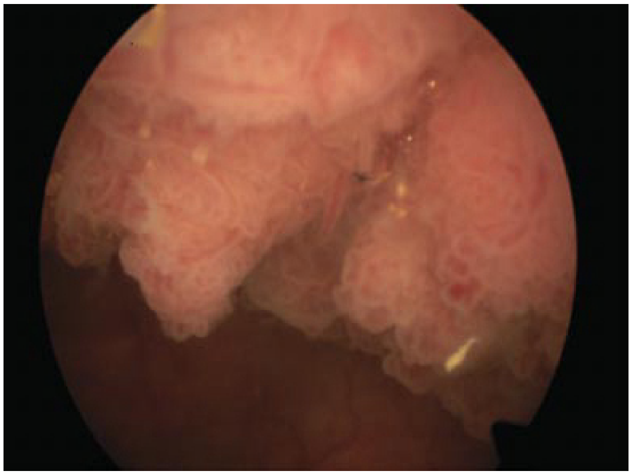

Figure 40.3 Sessile, larger, high-grade tumor with calcifications.

has been shown to be inadequate for accurate staging, and the underlying ureteral musculature can seldom be safely sampled ureteroscopically. Fortunately, stage and grade correlate closely, and accurate grading of the tumor is heavily relied upon to guide treatment options [7]. Cytology and biopsy are complementary tools in diagnosing and grading these tumors. While cytology is specific, it is less sensitive because most low-grade lesions will be missed. Higher grade TCC lesions are more likely to provide positive cytologic findings as the tumor cells have lost their cell–cell adhesion capabilities and demonstrate more easily identifiable morphologic changes. Direct ureteroscopic biopsy is highly sensitive but less specific. Thus, fluid aspirations for cytology and biopsies should be obtained from any suspicious lesion during ureteroscopy. A more extensive description of tissue sampling techniques is given in Chapter 41.

Benign essential hematuria

Evaluating patients with hematuria is one of the most common consultations for urologists. Hematuria initially can be divided into glomerular or nonglomerular causes based on urinalysis alone. Dysmorphic red blood cells, proteinuria, and red blood cell casts would indicate a probable glomerular cause of the hematuria and the patient should be referred to a nephrologist for evaluation and treatment. Nonglomerular hematuria can be caused by urologic problems such as tumors, stones, and urinary tract infections. Most causes of nonglomerular hematuria are determined with a standard hematuria evaluation, which includes upper urinary tract imaging and cystoscopy. If the hematuria evaluation is negative, additional studies might include complete blood count (CBC), coagulation studies, and platelet function studies to rule out bleeding diathesis. Referral to hematology for definitive evaluation can be done if bleeding diathesis is strongly suspected. A urine sample also should be sent for cytology and culture. If an obvious source of the hematuria cannot be determined through conventional studies, the condition is referred to as *benign essential hematuria* [5, 8].

Patients with benign essential hematuria can have frequent bouts of gross hematuria with clots and renal colic; otherwise, their long-term course is generally benign. Some will require repeated transfusions. Benign essential hematuria is found equally in men and women. Additional radiologic studies are frequently done to evaluate patients with benign essential hematuria. Renal arteriography and venography, and magnetic resonance imaging (MRI) arteriography may reveal larger vascular lesions. However, if the patient has already had a quality CT urogram, it is unlikely that a significant vascular lesion will have been missed. These additional imaging studies are usually of low yield because the most common vascular lesions causing benign essential hematuria are small venous abnormalities and hemangiomas [9]. These are seen better on endoscopic inspection of the upper urinary tract and will usually be missed on vascular imaging studies.

Other causes of chronic hematuria, including loin pain hematuria syndrome and the Nutcracker syndrome, should be considered [10–12]. Loin pain hematuria syndrome patients have intermittent pain and microscopic or gross hematuria. Although this diagnostic entity somewhat overlaps benign essential hematuria, loin pain hematuria syndrome has no specific anatomic findings and a significant psychiatric component, specifically associated with somatoform disorder. The Nutcracker syndrome is another potential cause of chronic hematuria. It is caused by venous hypertension of the left kidney due to compression of the left renal vein, between the aorta and the superior mesenteric artery [13]. It also has been described in patients with retroaortic left renal veins. Diagnosis is generally made by demonstrating venous hypertension during venography studies with a pressure drop beyond the point of compression of the left renal vein. Treatment is surgical, with repositioning of the left renal vein or renal autotransplantation.

In the past, some patients with benign essential hematuria required treatment with partial or total nephrectomy. With the advent of current flexible ureteroscopic instruments and techniques, most of these patients can be evaluated and successfully treated ureteroscopically.

The two most common ureteroscopic findings are renal hemangioma and venous abnormalities of the calyces (“minute venous ruptures”). Virchow was the first to describe renal hemangiomas during autopsy studies in 1867, suggesting they may be a cause of

chronic hematuria [8]. Rare reports of renal hemangiomas causing unexplained hematuria were published over the next century. Renal hemangioma can be large but are typically quite small, and most commonly occur on the tips of the renal papilla. They may be seen as small red or blue spots, or larger mulberry-like lesions. They are equally distributed between men and women, the right and left kidneys, and the upper and lower poles of the kidney.

Anatomic studies in the past have demonstrated a close anatomic association between the tributaries of the renal vein and the calyceal fornix. These venous sinuses are close to the surface at the calyceal fornix and may erode or rupture through the urothelium [14]. It has been postulated that these venous calyceal fistulas develop following periods of elevated pressure within the intrarenal collecting system [8]. They may be localized or diffuse, and have been described as venous ruptures, varices, renal forniceal hemorrhages, pyelovenous fistula, and hemorrhagic papillitis. They are among the more common causes of bleeding in patients with benign essential hematuria. Usually, these lesions are found in the kidney, rarely the ureter, and are equally distributed between men and women, right and left kidneys, and upper and lower poles. Ureteroscopic evaluation and treatment are more successful when the patient is actively bleeding, and when the lesions are discrete rather than diffuse.

A small number of patients evaluated ureteroscopically for hematuria will be found to have a TCC tumor or calculus. In other patients, nothing will be found. Despite no bleeding lesion being found, most studies report successful resolution of the hematuria after ureteroscopy. It has been suggested this could be due to resolution of unseen venous–calyceal communication because of increased intraluminal pressure during the ureteroscopy [16, 21].

Results with ureteroscopy for the evaluation and treatment of benign essential hematuria are presented in Table 40.1 [16–23]. Overall, the success rate for patients being treated ureteroscopically for benign essential hematuria is 90%.

Technique

The primary goal of diagnostic ureteroscopy is to obtain unhindered visual inspection of the entire upper urinary tract. There are some technical nuances that will help achieve this goal.

Some authors have reported performing flexible ureteroscopy without a working or a safety guidewire. This is possible with some newer flexible ureteroscopes that can be introduced into the ureteral orifice under direct vision without the use of a working guidewire [24]. This technique requires significant expertise and it is not possible with all flexible ureteroscopes in all patients. This technique may soon be the ideal “no touch” method for diagnostic ureteroscopy, and may become less challenging with future generations of ureteroscopes. However, at this time it is limited to certain ureteroscopes in the hands of experienced endourologists. For these reasons, we recommend and will review the standard technique of diagnostic ureteroscopy using rigid and flexible ureteroscopy to inspect the entire upper urinary tract (Table 40.2).

Bleeding from the urinary tract can occur anywhere from the upper pole of the kidney to the urethral meatus. Endoscopic evaluation of these patients begins with careful urethroscopy. Special attention is paid to the prostatic urethra, which can be a frequent site of benign gross hematuria. The bladder urothelium is carefully and completely inspected, and a bladder lavage for cytology is performed. The next cystoscopic step is careful inspection for bloody efflux from the ureteral orifices. When gross hematuria is present, this critical step will allow differentiation of unilateral and bilateral hematuria. Bilateral gross hematuria is typically “nonurologic” and a ureteroscopic evaluation likely will not be helpful.

Rigid and flexible ureteroscopy provide complementary access to the upper urinary tract [1]. While rigid ureteroscopy allows direct insertion and easy control of the ureteroscope, it does not allow easy access to the ureter superior to the iliac vessels. Without the ability to deflect the tip of a rigid ureteroscope, inspection of the intrarenal collecting system is impossible. Flexible ureteroscopy provides complete access of the entire intrarenal collecting system and upper ureter. However, inspection of the distal ureter is difficult because of buckling of the ureteroscope into the bladder. For this reason, rigid ureteroscopy is performed below the iliac vessels, and flexible ureteroscopy above. This combination of rigid and flexible ureteroscopy provides complete visual inspection of the entire upper urinary tract.

When performing ureteroscopy for the evaluation of hematuria, tumor surveillance, or other diagnostic purposes, it is important to recognize that the standard ureteroscopy technique can produce traumatic lesions that may be mistaken for pathology. Care should be taken to minimize this trauma to the ureter during ureteroscopy, as it will interfere with the diagnostic visual inspection. The effort to minimize trauma begins with using the smallest ureteroscope practical to avoid the need for dilation. Direct insertion of a rigid ureteroscope without prior dilation of the intramural ureter allows clean inspection of the distal ureteral mucosa. Avoiding the use of a guidewire during direct insertion of the rigid ureteroscope will further minimize trauma to the ureter.

The ureter is inspected with the rigid ureteroscope from the ureteral orifice to the ureter at the level of the

Flexible ureteroscopy
Over the previously placed wire
Inspect proximally from the level reached with rigid ureteroscope
Systematic inspection of intrarenal collecting system
Aspirate intrarenal urine for cytology
Biopsy any suspicious lesions
Lavage for cytology after biopsy
Fulgurate any bleeding lesion
Remove flexible ureteroscope and stent as indicated

iliac vessels. Care is taken to avoid excessive irrigation. Just enough irrigation is used to provide adequate distention of the ureter for visualization while preventing over-distention of the ureter and intrarenal collecting system. Even minimal over-distention of the collecting system can lead to small areas of urothelial hemorrhage and render the remaining inspection of the ureter for true sources of bleeding pointless.

Once the distal ureter is completely inspected to the level of the iliac vessels, further inspection of the proximal ureter requires flexible ureteroscopy. A guidewire is passed through the rigid ureteroscope, only as high as necessary into the ureter to allow placement of the flexible ureteroscope. Preferably, the guidewire is passed only to the level of the ureter that has been inspected with the rigid ureteroscope. The rigid ureteroscope is removed, leaving the guidewire in place, and the flexible ureteroscope is passed over this guidewire to the proximal extent of rigid ureteroscopic inspection. Flexible ureteroscopic inspection is then performed from this point and proceeds proximally in a retrograde fashion, generally without a safety guidewire. Again, this is to avoid trauma to the ureteral urothelium that might interfere with the diagnostic inspection. When using this technique of diagnostic ureteroscopy, a urothelium is being inspected that is "untouched" either by guidewires or ureteroscopes.

When inspecting the intrarenal collecting system, completeness is ensured with a systematic approach using combined endoscopic and fluoroscopic imaging. Irrigation with a dilute contrast mixed in normal saline allows precise documentation and navigation throughout the intrarenal collecting system. The intrarenal collecting system is inspected from the upper pole, moving systematically through the calyces to the lower pole, and each calyceal inspection is documented fluoroscopically. Care should be taken to avoid over-distention of the intrarenal collecting system to minimize urothelial trauma. Benign essential hematuria can be caused by small, subtle urothelial lesions. Any trauma from the guidewire, over-distention, or ureteroscope can prevent accurate visualization of these lesions. Likewise, prestenting should be avoided to prevent stent-related inflammation of the urothelium, which also will prevent accurate inspection of the upper urinary tract. A nontraumatic approach to diagnostic ureteroscopy is essential.

Ureteroscopy is truly an endoscopic extension of cystoscopic principles to the upper urinary tract. Ureteroscopic inspection of the upper urinary tract allows direct visualization and recognition of pathologic lesions, just as cystoscopy allows visual recognition of calculi, neoplasms, and other urothelial lesions. Visual inspection of the upper urinary tract via endoscopy permits visual recognition and differentiation of upper urinary tract pathology. TCC generally has an easily distinguishable appearance. However, some lesions, such as high-grade TCC, may be difficult to distinguish from benign soft tissue lesions such as inflammation. Ureteroscopic sampling for cytologic and pathologic analysis greatly improves our ability to distinguish malignant from benign soft tissue lesions. Direct irrigation through the ureteroscope with normal saline and aspiration for cytology is done whenever there is the possibility of a malignant lesion. Direct, precise biopsy, guided by ureteroscopic visualization of the lesion, permits a more accurate diagnosis than a brush biopsy guided by fluoroscopy alone. Biopsy of any suspicious lesions can be performed with 3F biopsy forceps for sessile lesions, or flat wire baskets for papillary lesions [6].

When treating patients with benign essential hematuria, when a source of bleeding is found, it should be fulgurated. This can be performed with either electrocautery delivered with a 2F blunt tip electrode (30–40 W coagulating current), or the neodymium:YAG laser. The holmium:YAG laser can be used, but at a wavelength of 2100 nm the laser energy is highly absorbed in water, resulting in relatively shallow tissue penetration of 0.4 mm. The holmium:YAG laser is primarily ablative, whereas the neodymium:YAG laser is more coagulative with a tissue penetration of 4–6 mm.

Conclusions

Improvements in the techniques and instrumentation of ureteroscopy have dramatically improved the ability to evaluate and treat patients with upper urinary tract abnormalities, including those who present with filling defects or benign essential hematuria. The entire upper urinary tract can be safely and reliably inspected endoscopically. Conditions such as renal hemangioma that may have resulted in a nephrectomy in the past are now better understood and treated in a renal-preserving minimally invasive manner thanks to these improvements in ureteroscopy. The future of diagnostic ureteroscopy is bright, and will likely continue to expand as ureteroscopes, tissue sampling methods, and methods of intervention incrementally improve.

CHAPTER 41

Ureteroscopic Diagnosis and Treatment of Upper Urinary Tract Neoplasms

Demetrius H. Bagley

Department of Urology, Jefferson Medical College, Thomas Jefferson University, Philadelphia, PA, USA

Introduction

Ureteroscopy is a major technique in the diagnosis, treatment, and surveillance of upper tract neoplasms. The introduction of fiberoptic illumination and imaging, and small rigid and flexible ureteroscopes, which were developed in the early 1980s, have made access to the entire upper collecting system routine. Combined with devices for tissue sampling and then tissue ablation, accurate diagnosis and treatment is possible. Other diagnostic studies, including radiologic, cytologic, and molecular techniques, can provide initial or supportive diagnostic information, yet remain secondary to endoscopy as the definitive study.

Upper tract neoplasms are relatively rare. Transitional cell carcinomas (TCCs) in the ureter and intrarenal collecting system account for approximately 5% of all TCCs [1]. They are, however, more common in patients with a previous history of carcinoma of the bladder [2, 3]. The presentation may be different in those with and without a history of bladder cancer. In those with no history of bladder cancer, the most common presentation (80%) is with hematuria, either gross or microscopic [1, 4, 5]. The lesion may be an incidental finding in 10–15% of patients, but flank pain can be seen in up to 30% of patients. Physical findings are rarely present unless the patient has metastatic tumor, unusual masses, or hydronephrosis secondary to obstruction.

Radical nephroureterectomy with removal of a bladder cuff has been considered the standard for treatment of upper tract tumors [6]. The application of endoscopic techniques to these lesions, initially in patients with a solitary kidney or compromised contralateral kidney, which have been considered imperative indications, has shown the feasibility of this treatment. Consequently, it has been performed increasingly in patients with a normal contralateral kidney [7, 8]. Evidence of progressive functional renal loss in patients undergoing nephrectomy for renal cell carcinoma can also be expected in patients losing their kidney to nephroureterectomy, and is a stimulus for nephron-sparing surgery [9].

Noninvasive diagnosis

Radiologic studies, including intravenous contrast studies to outline the collecting system, along with excretory urography or computed tomographic (CT) urography are the most useful noninvasive diagnostic techniques. A filling defect is the most common finding and may indicate an upper tract urothelial neoplasm. The differential diagnosis includes blood clot, lucent calculus, air bubble, fungal ball, sloughed papilla, external compression with a crossing vessel, or benign inflammatory or neoplastic lesion. One series using a multidetector CT scanner for CT urography in patients with gross hematuria demonstrated a very high sensitivity, specificity, and accuracy [10]. In some patients with a severe contrast allergy with nonvisualization of the collecting system, retrograde ureteropyelography may be indicated. However, this suffers from a low accuracy [4, 11].

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Renal ultrasound can define intrarenal calculi or hydronephrosis accurately and renal masses can also be demonstrated, but ultrasound is less useful to define small intraluminal soft tissue masses.

CT can be more helpful. It can accurately distinguish calculi from soft tissue masses. It is also helpful in demonstrating masses extending beyond the collecting system or enlarged lymph nodes. Inclusion of a pyelographic phase with reconstruction of the excretory system or an abdominal radiograph taken after the administration of contrast as an anteroposterior ureteropyelogram may be most useful in demonstrating intraluminal lesions [10, 12].

Magnetic resonance imaging (MRI) has similar limitations, especially in the cross-sectional mode [13]. The magnetic resonance urogram (MRU), designed to image the fluid of a distended collecting system, may be helpful in some patients with nonfunctioning kidneys or severe contrast allergies.

Cytologic study of voided urinary samples is of limited value because of the frequent equivocal and false-negative findings. It can be useful in detecting high-grade tumors which shed obviously malignant cells in the urine. The sensitivity of voided urinary cytology increases with an increasing grade of neoplasm, ranging from 11% for grade I to 83% for grade IV lesions [14]. Elective ureteral catheterization for a specific and localized upper urinary tract sample for cytologic study is occasionally indicated in patients with positive cytology without radiographic findings and with normal cystoscopy and bladder biopsy. However, routine ureteral catheterization to collect urine from a radiographically abnormal area is no longer indicated if ureteroscopy can be performed. Similarly, fluoroscopic-guided brush biopsy is rarely indicated when ureteroscopy is available.

One of the newest studies available is fluorescence *in situ* hybridization (FISH) of voided urine. The technique was first described for detecting bladder tumors and has variably been shown to be of value or unhelpful. Studies of voided urine to detect upper tract TCC have shown sensitivities higher than voided cytology, with similar or slightly lower specificity [15–17]. Ongoing studies suggest that there may be greater accuracy when the upper tract is sampled directly.

Endoscopic diagnostic techniques

Endoscopic evaluation of an abnormality in the upper urinary tract suspicious for a neoplasm includes inspection of the entire bladder and involved collecting system. Cystoscopic inspection of the bladder is an essential component in the evaluation of the patient with hematuria and/or filling defects because of the high risk of associated bladder tumors. It also provides access to the ureter for retrograde pyelography and for ureteral endoscopy. The upper tract is then studied after complete inspection of the bladder with biopsy of any suspicious lesions. A retrograde ureteropyelogram may give more information regarding the extent of the filling defect, suspicious lesion, or ureteral abnormalities that might affect access for treatment. A cone-tipped retrograde injection most efficiently outlines the entire collecting system without traumatizing the ureter itself. It may be necessary to use multiple injections of different concentrations of contrast with multiple radiographic views to define the extent of the lesion fully. Care should be used to prevent over-filling of the collecting system or overly dense radio-opacity, which can obscure filling defects. Initial ureteral catheterization without contrast study should be avoided since it can traumatize the specific lesion of interest and the otherwise normal ureteral mucosa.

A “no touch technique” should be employed to examine the involved upper collecting system. The distal ureter is first inspected either with a small rigid endoscope, preferably one small enough to pass into the orifice without other dilation, or with a flexible ureteroscope that can be passed into the ureter without dilation [18]. In this way, the ureter can be inspected without prior instrument trauma. When using a rigid scope, it is passed as far as possible into the lumen. In a young muscular male, the rigid endoscope can usually be passed throughout the distal third of the ureter, while in an older female it may pass easily to the level of the renal pelvis. A guidewire is then left in place as the endoscope is removed, passed only to the level of the ureter that has been inspected with a rigid scope. It should not be passed into the intrarenal collecting system as the tip of the wire can traumatize the calyx or the renal pelvis and obscure subsequent visual inspection. The smallest flexible ureteroscope is then passed over the guidewire into the ureter. If a small flexible ureteroscope can be passed directly into the ureter, the steps of rigid ureteroscopy and wire placement can be avoided.

The flexible ureteroscope is used to inspect the more proximal portions of the ureter not previously seen and the intrarenal collecting system. Inspection at that level should be systematic, going from the renal pelvis to the upper infundibula and calyces, and then to the mid and then the lower pole. In this way the risk of trauma to the mucosa with the endoscope is minimized.

Continuous irrigation with saline is maintained through the working channel of the ureteroscope to clear the field of view. Iodinated contrast can be used in the irrigant to outline the collecting system for fluoroscopic monitoring. Positioning of the flexible ureteroscope throughout the collecting system can then be confirmed fluoroscopically. Care must be taken to avoid

overfilling the collecting system, since this can induce submucosal hemorrhage and rupture of the fornices. When adding contrast through the endoscope within the collecting system, the irrigant present should be removed. Lines of refraction will be visible as fluids of two different densities mix. This can be avoided by minimizing the mixing.

If there is a specific lesion to be examined, such as a filling defect or a point of obstruction, then the distal portion of the urinary tract should be inspected first, followed by the lesion itself in order to inspect it within a clear visual field without other manipulation that may cause bleeding and obscure the field of view. In many cases, visual inspection alone can provide a diagnosis [19–22]. For example, the appearance of a calculus will readily distinguish it from a low-grade papillary tumor. An extrinsic mass can also be readily distinguished. A vascular impression on the renal pelvis will become more prominent as the pelvis is emptied and less prominent as it fills. In addition, an arterial impression can be seen pulsating. In each case, irrigant with contrast should be used so that fluoroscopy can demonstrate the tip of the ureteroscope at the filling defect. In this way, correct visualization and identification of the lesion can be confirmed.

Epithelial neoplasms may have totally different appearances. Low-grade TCCs have a typical papillary appearance, similar to the same lesions in the bladder (see Videos 41.1, 41,2A,C, and 41.3). High-grade TCCs may be more sessile and less papillary, often with necrotic or inflammatory debris on the surface. However, these differences are not consistent. El-Hakim *et al*. found an accuracy of only 70% in determining the grade of an upper tract neoplasm from appearance alone [23].

Benign lesions can also be diagnosed endoscopically but without perfect accuracy. Fibroepithelial polyps located within the pelvis and inverted papillomas throughout the upper collecting system have been seen to have a smooth, rounded surface [24]. The appearance may give an impression of an intact epithelial layer. These features have not been prominent enough to allow visual identification, but they are strongly suggestive. All observed benign lesions, including fibroepithelial polyps, inverted papillomas, and hemangiomas located in the ureter or the ureteropelvic junction (UPJ) can be narrow, elongated, and worm-like.

In some specific instances, visual inspection alone may not be adequate to diagnose a neoplasm. High-grade urothelial neoplasms can be confused with inflammatory lesions or may be obscured by tumor growing submucosally or proximal to obstructive edema. There may be calculus material on the surface of a neoplasm with the resultant appearance of a solid calculus. Other tumors with a necrotic surface can look the same as a soft, infection stone covered with inflammatory debris. In these and many other situations, other interventional endoscopic maneuvers are necessary to obtain an accurate diagnosis.

Aids to visual diagnosis of neoplasms, such as HexFix or narrow-band imaging (NBI), have been used in the bladder to detect carcinoma *in situ* or additional exophytic tumors. These techniques have been used in the upper tract only in short series without definitive findings [25].

Endoscopic biopsy

Ureteroscopic biopsy is an important procedure to sample neoplasms in the upper urinary tract and give a tissue diagnosis. It is of value in determining the malignancy of a lesion and the grade of a TCC. Ureteroscopic biopsy is limited because of the size of the working channel within the ureteroscope and the subsequent limitation in the size of the biopsy instrument that can be used. For example, a piece of tissue obtained with 3F cup biopsy forceps will be less than 1 mm in diameter, which is usually too small to be prepared for histologic study using standard techniques; it is often lost in the process (see Video 41.1A). In contrast, it is a relatively large fragment of tissue for cytologic techniques. It can be prepared as a cell block, and stained and examined as a histologic preparation to give a diagnosis and information on grading.

Several different biopsy instruments and techniques are available. Abdel-Razzak *et al*. evaluated samples from 55 procedures in 44 patients with a possible diagnosis of upper tract TCC [26]. They compared the diagnostic yield, considering only those samples that were specifically positive or negative for malignancy. Those that were "suggestive" or equivocal were not considered diagnostic. The techniques compared aspiration of urine at the level of the lesion, wash and aspiration with saline solution of the area of the lesion, and direct tissue sampling with brush, basket, or biopsy forceps. The tissue sampling techniques gave the best yield, particularly the flat wire basket for large friable tumors and the cup forceps for more sessile lesions. The brush was less effective and under endoscopic vision was observed to move the more flexible tissue without removing fragments. It may be more useful with flat or sessile lesions. Aspiration and wash proved to be valuable in providing a diagnosis for some patients in whom the other sampling techniques were inconclusive.

A flat wire basket is quite effective for removing large fragments of papillary tissue with a small diameter ureteroscope (see Video 41.2A–C, 41.6). Under endoscopic vision, the basket is placed on the tumor and partially closed. The entire unit, consisting of tumor sample, basket, and ureteroscope, is then removed from the ureter and bladder. In this way a large sample can be

removed (up to 1 cm in diameter), which is adequate for cytologic or histologic study. The ureteroscope is then reinserted to repeat the inspection and biopsy or to treat the neoplastic lesion.

One of the most important steps in handling the tissue for pathologic diagnosis is to work closely with the cytopathologist [27–30]. Samples are examined with both a smear and cytospin preparation. If there is any macroscopically visible tissue in the sample, a cell block is also prepared. This sample, if adequate for cell block, often demonstrates both the architecture of the neoplasm and the individual cells to allow grading of TCC. Multiple samples of the lesion are taken. In addition, urine and saline wash samples at the lesion before and after biopsy and/or treatment are also obtained (Table 41.1).

Grading

Grading of upper tract TCC is important in determining the prognosis and directing therapy. The grade obtained from ureteroscopic biopsy has been shown to reflect the grade of the overall tumor with reasonable accuracy. In 42 patients, Keeley *et al*. found that the grade seen on a ureteroscopic biopsy prior to surgical treatment matched that in the final pathologic specimen in 86% of cases [31]. Danashmand *et al*. showed an overall accuracy of 90% in patients who had surgery early after biopsy or within 2 months after ureteroscopic diagnosis [32]. Combined cytology and ureteroscopic biopsy have been particularly valuable in accurately diagnosing patients with grade II TCC [33].

Staging

Accurate staging of upper tract TCC has not been possible with endoscopic techniques alone. The search for metastases includes the usual abdominal CT scans or MRIs and chest radiographs. Determining the depth of invasion of the primary tumor or other simultaneous lesions remains difficult, and most series have not reported accuracy in determining it. One series advocated multiple deep biopsies with cup forceps in an attempt to determine the presence of tumor in the lamina propria [34].

The grade of the primary tumor has often been associated with stage, but it cannot be considered to be truly accurate staging. In Keeley *et al*.'s series, increasing stage correlated with increasing grade seen on ureteroscopic biopsy [31]. Brown *et al*. also found that the grade on endoscopic biopsy correlated with the final pathologic stage in nephroureterectomy specimens [35]. Other series of patients treated surgically have also demonstrated the relationship of increasing stage with increasing grade [36].

Endoluminal ultrasound has been used in one series in an attempt to determine the depth of invasion [37]. It has shown some value but is severely limited by the availability of the instruments.

Complications

There remains some concern that the ureteroscopic biopsy of an upper urinary tract neoplasm can disseminate tumor cells locally or systemically. The possibility of pyelovenous or pyelolymphatic backflow has been cited as a possible mechanism. In a single case report, tumor cells were found outside the kidney in a nephroureterectomy specimen after ureteroscopic biopsy [38]. However, in a review of 13 nephroureterectomy specimens following ureteroscopic biopsy, no unusual metastatic pattern was seen [39]. In a well-controlled study of 96 patients, Henden *et al*. found no difference in long-term or disease-specific survival in patients with upper tract TCC who had surgical treatment preceded either by ureteroscopic biopsy or not (Table 41.2) [40]. Hara *et al.* reported on 50 patients who had ureteroscopic biopsy without development of metastatic disease [41]. From these series it can be concluded that ureteroscopic biopsy can be a safe and very valuable procedure without any documented evidence of tumor dissemination.

Selection of patients for ureteroscopic biopsy

Ureteroscopic biopsy is of value in any patient with an upper tract filling defect in whom the diagnosis is questioned. Voided urinary cytology is a less than definitive (positive) diagnostic test for malignant cells in patients with a filling defect. The presence of individual malignant appearing cells (positive cytology) indicates either carcinoma *in situ* or a high-grade neoplasm. Biopsy may be avoided in patients with cytology that is definitively

positive for malignant cells and who have a large irregular upper tract filling defect, findings that can be considered classic for TCC. However, even these patients should have endoscopy to rule out associated bladder tumor.

Ureteroscopic treatment

The advent of ureteroscopic access to the entire upper urinary tract has also provided options for the treatment of upper tract neoplasms. These procedures are based on the extension of diagnostic procedures. Many devices can be placed through the working channel of the ureteroscopes to treat neoplasms [42]. These include graspers, electrodes, and laser fibers. There has been considerable interest and wide acceptance of these techniques for the treatment of some upper tract neoplasms. The techniques for treatment and selection of patients are evolving as the value of this approach is being defined in relatively small series of patients.

The rationale for conservative endoscopic therapy of upper tract neoplasms was based initially on the success of other conservative treatment modalities for similar lesions. These series have defined the role of conservative treatment in the high-risk patient and have extended such therapy to other specific lesions. Conservative surgical techniques have been used to treat upper tract tumors with mixed results, depending on the nature of the tumor and its location. Endoscopic treatment is a natural extension of these nephron-sparing procedures, evolving only as the instruments have become available. Similarly, these techniques can be considered an extension of endoscopic procedures used at the bladder level for the treatment of TCC of the bladder. Since these series have not shown a prohibitive risk, other series in progress will continue to define appropriate applications of endoscopic therapy. There has been considerable growth in the application of endoscopic treatment of upper tract tumors with survey evidence of it being performed by academic and nonacademic urologists [43].

Natural history and prognosis after surgical therapy

The natural history of neoplasms in the upper urinary tract must be considered in order to define the optimal mode of therapy. TCC constitutes the vast majority of endoluminal tumors in the upper collecting system; there remain a few benign lesions which can be considered separately. Since ureteroscopic access will allow treatment of endoluminal lesions only, TCC is, for practical purposes, the only malignant neoplasm to be considered for treatment.

The behavior and prognosis of upper tract TCC , in both the ureter and the intrarenal collecting system, has repeatedly been shown to relate to the grade and stage of the lesion. In a series by Charbit *et al*., the overall survival rates at 5 and 10 years after treatment were 67.3% and 64.9%, respectively [36]. Only 19.5% of patients died of metastases from the upper tract tumor, 86% died within 1 year postoperatively, and the remainder died within 2 years. Among those with tumor-related deaths, 90% had high-grade tumors (grade II or III/IV) and 86% had presented with muscle invasion. Nielsen and Ostri reviewed 36 patients treated surgically for primary carcinoma of the renal pelvis and found that six of 22 patients (27%) with grade II/IV TCC and eight of 11 (80%) with grade III/IV lesions died from their disease [44]. Both of the patients with grade IV TCC also died of this disease. The prognosis was statistically significantly poorer for patients with grades III and IV Ta than those with grade II. Survival of 49 patients with grade I Ta of the ureter or renal pelvis collected at the Mayo Clinic over a 22-year period was identical to that of an age-matched control group [45]. In contrast, survival with higher grade Ta correlated with tumor stage and grade, and was consistently lower than in a control group [46].

The close relationship between grade and stage is also reflected in the prognosis. Mufti *et al*. found that survival of patients with superficial well-differentiated tumors was greater than 90% in groups treated either by total nephroureterectomy or by more conservative resection [47]. In the series of Nielsen and Ostri, only three patients (14%) with grade II/IV lesions had invasion of connective tissue while 10 (91%) with grade III lesions and both patients with grade IV had invasion [44]. In the series by Charbit *et al*., 79% of the grade II/III tumors had invaded into or beyond the muscle layer [36]. Lymphadenectomy was negative in all patients with low-grade tumors in whom it was performed, while 39% of those in patients with higher grade tumors were positive.

The grade of the primary lesion also indicates the extent of mucosal abnormality. McCarron *et al*. systematically mapped nephroureterectomy specimens and found that the grade of the principle neoplasm paralleled the extent of epithelial disturbance in the otherwise normal appearing urothelium [48]. They found that high-grade carcinomas were associated with severe epithelial changes and low-grade cancers with hyperplasia only. Cytologic study of specimens collected either from the upper tract (17 of 30 cases) or bladder urine (13 cases) accurately reflected the grade of the principle neoplasm. It also indicated the presence of both contiguous and remote abnormalities. Among seven patients with grade I/III tumors, six had negative cytologic studies and one was suspicious for carcinoma. However, among those with grade III lesions, 10 were positive for malignant cells, three were suspicious, and only one was negative.

Mazeman reported that a multiplicity of tumors formed a negative prognostic factor; only 20% of patients with multiple tumors survived for 5 years while 37% with single tumors survived for 5 years [49]. Survival was the same whether the primary tumor was within the renal pelvis, intrarenal collecting system, or ureter.

Standard surgical treatment of TCC of the upper urinary tract has been nephroureterectomy including a cuff of bladder. High recurrence rates have been noted when a less extensive operation has been performed, particularly with more proximally located lesions. Mazeman noted that there was a recurrence rate of 19% after total nephroureterectomy [49]. This increased to 24% after subtotal nephroureterectomy, 32% after partial nephroureterectomy, and 48% after nephrectomy alone. Recurrences were noted to be distal to the primary tumor in any part of the urinary tract, the majority in the bladder around the orifice. There is a low rate of occurrence in the contralateral kidney. The risk of bladder cancer in patients presenting initially with an upper tract urothelial tumor was approximately 9% and that of a contralateral urothelial tumor was 1%. In those with a previous history of bladder tumors, the risk of another vesical lesion was 53% [36]. Among patients with grade II or III/IV lesions in a Mayo Clinic series, the incidence of bladder tumor was 30% [46]. Based on these and similar findings, recommendations for follow-up have included cystoscopy at intervals of 3–4 months and imaging of the remaining upper tracts at 1 year. Recommendations for continued evaluation of the upper tract vary after that period.

There has been a very strong trend toward laparoscopic nephroureterectomy rather than open surgical treatment.

Conservative surgical therapy

Conservative, nephron-sparing surgery for upper tract TCC has been attempted in special circumstances in patients with a solitary kidney who are not candidates or who refuse to become anephric, and those with a compromised contralateral kidney, including bilateral tumors. There is also evidence that low-grade and -stage distal ureteral tumors can be treated by distal ureterectomy alone.

Major series have reviewed the results of local surgical treatment of upper tract tumors both in the renal pelvis and the ureter. Generally, there has been a higher recurrence rate after the treatment of renal pelvic tumors and a much lower rate for ureteral tumors. Mazeman [49] and Zincke and Neves [50] reported recurrence rates of 45–65% after the local resection of renal pelvic TCC, and 15–16% after resection of ureteral lesions. The lesions treated, however, included a wide range of grade and stage. These and other series have found that distal ureterectomy for low-grade TCC in the distal ureter is often curative [45, 51–53]. Based on these results, some have recommended distal ureterectomy as primary therapy for distal ureteral lesions.

In summary, recommendations for conservative surgical therapy of upper tract TCC include high-risk patients, and those with a solitary kidney, a compromised contralateral kidney, including bilateral tumors, or overall compromised renal function. Also included are those in whom nephroureterectomy would be an overwhelming medical risk. Low-grade and -stage, distal ureteral tumors can be successfully treated with distal ureterectomy [45, 51–54].

Diagnosis, staging, and grading

Diagnosis of an upper tract lesion suspicious for neoplasm is essential before considering any form of therapy. In brief, it is now usually possible to diagnosis upper tract filling defects which have been detected by radiographic studies but await endoscopic evaluation and sampling for a final diagnosis.

Grading of TCC has also been possible with endoscopic sampling combined with cytopathologic techniques [55–57]. Others have previously demonstrated that high-grade lesions more frequently shed cells giving positive urinary cytologic findings [45, 48, 57]. Since low-grade tumors may shed papillary structures, indicating the presence of low-grade malignancy, a distinction in grading can sometimes be made on the basis of cytologic findings from the urine alone. This has been extended to endoscopic sampling techniques.

Staging of TCC in the upper tract has been important to direct treatment and indicate prognosis. A search for metastatic disease and renal parenchymal invasion by TCC is the same whether the treatment to be considered is surgical or endoscopic. Only when there is a decision to be made regarding radical or conservative (including endoscopic) therapy does it become important to determine the stage preoperatively by learning whether there is local invasion by the neoplasm. The techniques available have generally failed in any attempt to establish the stage of low-stage lesions.

Endoscopic therapy

Endoscopic therapy of TCC is familiar and well accepted for lesions in the urinary bladder. The concept is new only when applied to lesions in the upper urinary tract. The instruments and techniques for endoscopic access for both diagnosis and treatment, as well as follow–up, are now available. The size of endoscopes employed, the ablative devices available, and the access with rigid or flexible ureteroscopes must be considered in any endoscopic approach to upper tract tumors. The neoplasm

Table 41.3 Tumor factors used in the selection of patients for ureteroscopic treatment.

Cytology	Negative	Positive

itself, including its diagnosis, grade, location, and size, must also be considered in any decision for endoscopic treatment in an individual patient (Table 41.3). Ureteroscopy has become the major endoscopic technique for the diagnosis and treatment of upper tract neoplasms. However, it is used with the complementary techniques of percutaneous nephroscopy for resection of larger neoplasms and laparoscopic nephroureterectomy or distal ureterectomy.

Several techniques are available that can be applied to the treatment of upper tract neoplasms ureteroscopically. These techniques, which can remove or ablate tissue within the upper tract using rigid or flexible ureteroscopes, include mechanical removal, electrosurgical resection, fulguration, and laser therapy. These are considered in greater detail because of their importance in treating neoplasms within the upper urinary tract.

The techniques used for the ureteroscopic biopsy of tumors result in the removal of tissue volume. A flat wire basket can remove several millimeters of papillary tumor with each application (see Video 41.6). Although the cup biopsy forceps remove a small volume with each bite, repetitive sampling can remove a small tumor (see Video 41.1A). The base of the tumor can then be coagulated with one of the other instruments (see Video 41.1B).

Electrosurgical techniques similar to those used in the bladder have been applied for small distal ureteral neoplasms. Historically, resection was the first to be used for treatment of upper tract neoplasms [58, 59]. Rigid ureteral resectoscopes, similar to a long version of a pediatric resectoscope, can be used in a similar fashion to other resection procedures for tumors in the distal ureter. The resectoscopes are relatively large, approaching 12–13F. The loop takes a small bite of tissue and it may become necessary to clean the loop before removing the next piece of tissue. This is often a slow procedure. After resection, the base of the tumor can be lightly fulgurated. Extreme care should be taken to avoid resecting through the full thickness of the ureteral or renal pelvic wall, and also to avoid fulgurating a large area of the ureter, which can result in scarring and stricture formation [60]. Electroresection has been superseded by other more efficient techniques.

The other major electrosurgical technique is simple fulguration with an electrocautery probe. This technique is suitable for very small lesions or for the base of a tumor after removal of the bulk of the volume of the lesion. Small probes of 2–3F are available and can be passed through the channels of small-diameter rigid or flexible ureteroscopes. Again, care should be maintained to avoid fulgurating large areas of the ureter. This electrocautery technique is also useful for lesions within the intrarenal collecting system, particularly in the lower pole medially where the laser fiber cannot be deflected by the ureteroscope to approach the tumor. The 2F electrode is slightly more flexible and can fulgurate with lateral contact rather than the directly forward approach needed with laser therapy (see Video 41.5B).

Laser techniques have been widely applied for the treatment of upper tract neoplasms and have proven to be the most efficient technique. Small fibers of either 200- or approximately 400-µm core diameter can be passed through the flexible ureteroscope. The two major lasers currently available for urologic application can effectively treat upper tract tumors with coagulation, ablation, and resection. The neodymium (Nd):YAG laser is the first laser to be used both for treatment of bladder tumors and for ablation of renal pelvic and ureteral neoplasms. It was first used with open surgical techniques to ablate TCC in the renal pelvis and intrarenal collecting system [61]. Long-term cure without recurrence has been achieved with this technique. The Nd:YAG laser was subsequently used ureteroscopically to ablate TCC of the ureter [62]. In a comparative series, Schmeller and Hoffstetter demonstrated the success of laser ablation of upper tract tumors with the development of fewer ureteral strictures than after electrocoagulation [63].

The Nd:YAG laser can penetrate several millimeters into tissue after several seconds of exposure. This can be controlled by positioning the fiber onto the tumor without directly aiming it toward the wall of the ureter, and by moving the fiber across the surface of the tissue to avoid prolonged exposure. Ureteral damage is limited since the laser fiber and beam are aimed at the tumor parallel to the surface of the kidney. Within the kidney, especially the renal pelvis, where there is a greater surface area and less risk of scarring and stricturing, the neoplasm can be coagulated safely with the Nd:YAG laser [64] (see Video 41.3). The laser is activated at 20–30 W on continuous mode and moved over the surface to coagulate the tissue. The effect can be seen as the color of the tissue changes to white. The laser fiber should not touch the tissue when it is activated because the tip will then char. For a relatively large lesion obstructing the ureter or an infundibulum, it may be necessary to remove some of the coagulated tissue to determine whether viable tumor remains after a single application. Since the

laser can penetrate to a depth of approximately 5–6 mm, it may not affect the entire depth of the tumor. Coagulated tissue is removed with a grasper or basket to expose portions of the tumor otherwise not visible ureteroscopically. The remainder of the tumor is then treated similarly. There have been no reports of major renal or vascular injury or damage to associated organs from forward scatter of the Nd:YAG laser used in the renal pelvis.

The holmium (Ho):YAG laser has been widely applied for urologic indications. It is a solid-state pulsed laser that can fragment calculi, and coagulate, ablate, and remove tissue. This laser produces light at a wavelength of 2100 nm, which can be carried along low water content fiber. The laser energy is absorbed within less than 0.5 mm of tissue or fluid and has essentially no risk of forward scatter. The effect observed is the only tissue effect achieved (Figure 41.1). This laser is particularly useful for ureteral lesions since it can ablate and remove a visually occlusive neoplasm to open the lumen for inspection more proximally [65–67] (see Video 41.4).

The laser fiber must be placed in contact with or very close to the tissue to be treated. The laser is then activated at energies from 0.5 to 1 J at a frequency of 6–10 or even 15 Hz. Irrigation is maintained to clear the visual field of tissue debris. It is often necessary to discontinue treatment to allow the field to clear, since considerable debris is formed during treatment. Bleeding occurs occasionally and can be controlled better at lower energies or by moving the fiber slightly away from the tissue to diffuse the laser beam and improve coagulation. There is also clinical evidence that a longer pulse duration, such as 700 ms, rather than the 350 ms often used for lithotripsy, will also improve coagulation (see Video 41.5A). The very limited penetration allows precise control and the laser, thus, can be used for lesions located at the level of the iliac vessels and the renal pelvis near the renal vessels. Great care is employed to avoid ablation and resection through the wall of the ureter or renal pelvis itself.

The argon laser has major theoretical advantages for endoscopic treatment as well. Wavelengths of 488–514 nm have been used to treat superficial bladder cancer and also ureteral neoplasms. The penetration is limited to 1 mm and the laser light can be delivered with a fiber of 300 or 600 μm diameter. Johnson reported treating tumors with continuous wave argon laser energy with a quartz fiber, utilizing a contact mode with the power set at 5 W [68]. There was satisfactory ablation of tumors in all three patients, but other confirmatory reports are still not available.

The thulium laser has a wavelength of 1.946–2.013 μm with the advantage of coagulation similar to the Nd:YAG laser and cutting capabilities. It does not have the ablative effect of the holmium laser. Only preliminary reports, which have been favorable, are available.

These lasers can also be used in combination. The effects of the Nd:YAG and Ho:YAG lasers are complementary. The Nd:YAG laser can be used to coagulate the major volume of tumor since it penetrates several millimeters and can achieve coagulation effect within the depth of the tissue. The coagulated tissue can then be removed mechanically or even more effectively with the Ho:YAG laser. The Ho:YAG laser can then be used to resect the tissue to the level of the wall of the ureter or renal pelvis. Thus, the benefits of each device can be used to the best advantage.

Results of treatment

The results of ureteroscopic treatment of upper tract TCC have been reported in several relatively small series. The techniques used for treatment, the location and characteristics of the tumors, and follow-up techniques and duration have varied widely. In the early report of Huffman *et al*. on the treatment of upper tract urothelial tumors, eight patients with low-grade tumors were treated by ureteroscopic fulguration or resection [58]. Surveillance was continued every 3 months with an average follow-up of 21 months. There were asynchronous recurrences in three patients which remained low grade and no patient required surgical treatment during the study period. Grossman *et al*. reported a higher recurrence rate in patients all treated endoscopically [69]. Among their eight patients, two were eventually treated surgically. One required a nephroureterectomy after the ureter could not be negotiated with the ureteroscope for treatment of a recurrence.

Several larger series since these earlier reports have expanded the acceptable limits of treatment, including larger proximal lesions, and some have included higher grade tumors. Overall, this has resulted in a relatively high recurrence rate with a wide variation and an increasing need for nephroureterectomy, but stable development of new bladder tumors [70–81].

Recurrences

TCC of the upper urinary tract recurs at significant rates, just as locally treated bladder tumors do. There too it is impossible to determine whether the recurrence is the result of implantation of cells from the original tumor or if it is related to a field change in the urothelium. Successful treatment depends upon thorough treatment of the primary neoplasm without irreversible damage to the organ system, coupled with the lack of local recurrence of the neoplasm as well as a lack of metastases. Several factors come into play in the adequacy of treatment.

Conservative surgical treatment with open excision of solitary upper tract lesions also results in significant

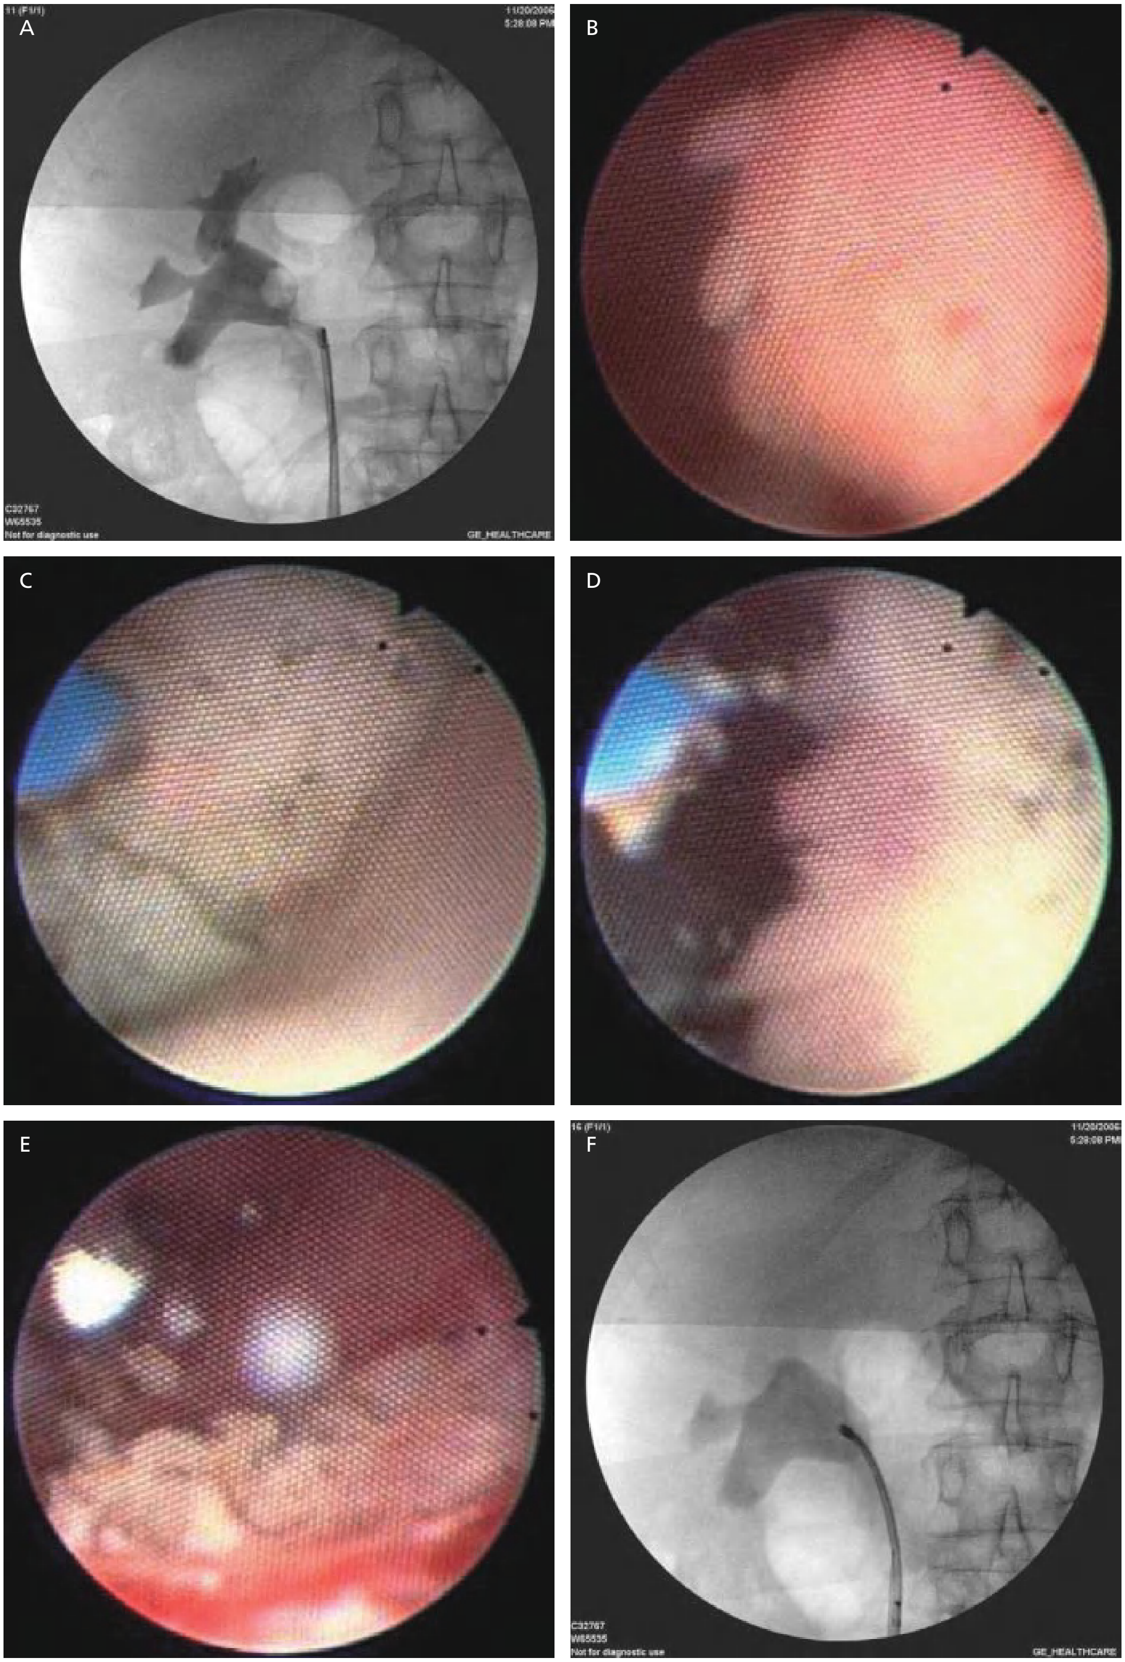

Figure 41.1 (A) Fluoroscopic view of the right collecting system with contrast demonstrates the filling defect based on the medial wall. (B) Endoscopic image of the grade I–II transitional cell carcinoma before treatment. (C) Tumor is coagulated with a Nd:YAG laser. (D) Coagulated tissue is resected with the Ho:YAG laser. (E) Tumor has been resected to the base along the contour of the renal pelvis. (F) Fluoroscopic view of the renal pelvis after ureteroscopic resection demonstrates the absence of a mass or evidence of extravasation.

local recurrence. As noted above, the recurrence for ureteral lesions is approximately 12–18% and higher when more proximal lesions were removed. Renal pelvic lesions treated surgically recur at an even higher rate of 48–66% [49, 50, 79].

In collected series reporting ureteroscopic treatment of upper tract tumors during the early experience through 1995, there was a higher recurrence rate for renal pelvic lesions (40%) than ureteral lesions (25%). However, during the following 5 years, there was an increase in the recurrence of ureteral tumors (43%) with renal pelvic tumors stable at 37%. During that time, the rate for nephroureterectomy increased from 4% to 14%. Thus, it can be speculated that the difference is related to the ureteroscopic treatment of larger and more proximal ureteral lesions in the later years. Higher recurrence rates can be expected from these lesions.

More recent studies are more difficult to compare since they have included a wide range of tumor sizes and even higher grade lesions. Recurrences have been seen in up to 80% or more of patients in some series. We have found that most of the recurrent lesions are small and can be treated endoscopically. Only when there are extensive and rapid recurrences does nephroureterectomy become necessary (Table 41.4) [83–85].

These series are also characterized by high disease-specific survival, with the two notable exceptions of the series reported from the Mayo Clinic of patients presenting initially with bladder tumors, and in those in whom imperative indications such as a solitary kidney prompted their endoscopic treatment. It is notable that in many of the patients, biopsy confirmation was not available and high-grade recurrences developed [86, 88, 89].

Several characteristics of primary upper tract TCC appear to be related to the risk of recurrence (Table 41.5). Some of these characteristics are similar for to those for risk of recurrence for bladder tumors. Recurrent disease is more likely for tumors over 1.5 cm in diameter than for smaller lesions. There is also a higher risk of recurrence for high-grade tumors treated either ureteroscopically or by open surgery. There is evidence that positive urinary cytology at the time of treatment is a poor prognostic sign. The effect of the location of the primary tumor, whether in the intrarenal collecting system or ureter, has been inconsistent, with some series reporting a higher rate for intrarenal neoplasms and others finding no difference or more frequent recurrence after ureteral primaries. However, multifocal lesions have consistently been seen to be associated with more frequent recurrences, both in the upper tract and in the bladder.

Bladder tumors

There is significant risk of new bladder tumors developing in patients with upper tract neoplasms. In a summary of several series reporting laparoscopic and open nephroureterectomy, the subsequent bladder tumor rate was 31.1% after laparoscopic treatment and 30.1% after open surgery. However, there was a wide range in each group: 10–55% in the laparoscopic group and 15–45% in the open surgical group [90]. Additionally, one series compared bladder recurrences after retroperitoneoscopic or open nephroureterectomy without finding any difference [91]. Among patients with upper tract tumors treated ureteroscopically, the average subsequent bladder tumor occurrence rate was 38.7%. In two series of patients without previous bladder tumors, the rate was 34% and 33%, respectively (Table 41.6).

Some series have noted that the bladder tumor rate is related to the grade of the primary tumor, while the effect of grade was not considered in others. One report

**Reviewed series to 2001.

found that the rate of new bladder tumor was related to a previous history of bladder cancer, where a 53% bladder tumor rate was noted [36]. There appears to be no major difference between the rate of bladder tumors seen after ureteroscopic treatment or open or laparoscopic nephroureterectomy, although it is a few percentage points higher in the ureteroscopy group. One review of 89 patients with total nephroureterectomy for localized TCC of the upper tract showed a direct effect of tumor multiplicity and surgical modality, with bladder tumor rate with laparoscopic treatment higher than with open surgery. An inverse relationship between tumor size and pathologic stage on subsequent development of bladder cancer was also noted [92].

Large tumors

Large neoplasms of the upper tract can be treated successfully ureteroscopically in some patients. It may be necessary to stage treatment at intervals of approximately 8 weeks and to use a combination of Nd:YAG laser coagulation or electrocoagulation with holmium laser resection. If visibility deteriorates with bleeding or tumor debris, it may be impossible to distinguish the margin of the tumor. The second resection may allow more precise treatment. Some tumors that regrow too rapidly or are too large to be treated ureteroscopically may require a percutaneous nephroscopic procedure or even nephroureterectomy.

High-grade tumors

In general, high-grade tumors have not been considered good candidates for ureteroscopic treatment because of the risk of invasion, metastatic disease, and rapid recurrence. However, in some specific patients, ureteroscopy may be the preferable option for the management of a high-grade upper tract neoplasm. The same ureteroscopic techniques would be employed. There is some evidence that high-grade lesions will recur more frequently, but long-term successes have also been reported [77]. The patient must be informed of the risks of resection and be able to participate in subsequent endoscopic surveillance. A survey of endourologists showed that 77% favored a distal ureterectomy for a large distal ureteral tumor. Only 21% thought that ureteroscopic ablation for such a lesion would be the first choice [43].

Normal contralateral kidneys

Initially, the ureteroscopic treatment of upper tract TCC was limited to patients with a solitary kidney or abnormal contralateral kidney. Based on the success of this experience, ureteroscopic treatment has been extended to patients with a normal contralateral kidney. The feasibility of this approach was demonstrated in studies looking specifically at patients who had two kidneys. More recently, patients with two normal kidneys are generally included in reported series.

Elliott *et al*. reviewed 21 patients with two kidneys and found that 37% developed local recurrence at an average of 7 months after treatment [75]. There was a 46% recurrence rate among 13 ureteral tumors and only 12% (one of eight) for renal pelvic tumors. There was, however, a high mortality rate with 11 of 20 patients dying of unrelated causes, with one dying from invasive bladder cancer. There were no deaths related to the endoscopic tumor treatment or the upper tract neoplasm. Only four patients (19%) required nephroureterectomy. The high unrelated mortality rates suggest that these patients are generally at high risk.

In a series by Chen and Bagley, 23 patients with two functional kidneys were treated ureteroscopically [93]. The patients had several recurrences, but there was no significant grade increase and no patient developed metastatic disease. At the time of their follow-up, 17% had an ipsilateral recurrence and 5% (one patient) had developed a new contralateral neoplasm. However, 61% of patients were free of disease. Four (17%) had required nephroureterectomy.

Matsuoka *et al.* reviewed their experience with ureteroscopic treatment of upper tract tumors and found that there was a higher recurrence rate (86%) among patients treated for a strong indication, such as a solitary kidney, while it was only 20% in those treated electively [78]. Thus, the results again appear to be related to patient selection.

Thompson *et al.*'s series reported 83 patients with normal contralateral kidneys and demonstrated a recurrence rate of 55% [87]. The last follow-up noted that 33% of patients required nephroureterectomy and 11% had died from TCC. However, it was noted that over half the

patients had a diagnosis based on visual inspection alone and 21% of those had developed grade III TCC during follow-up.

In summary, ureteroscopic treatment of upper urinary tract TCC can be performed safely and effectively with preservation of renal units even in patients with a normal contralateral kidney. The same factor of long-term function used to promote partial nephrectomy for renal cell carcinoma should be considered also to apply to patients who have TCC. Every effort should be made to preserve renal mass when possible.

Surveillance

Surveillance after ureteroscopic treatment of upper tract neoplasms is essential because of the high recurrence rate. Almost every paper reviewing experience with this treatment has cautioned that endoscopic surveillance is necessary. Cystoscopy has been well-established as the standard technique to evaluate for new bladder neoplasms after surgical treatment of upper tract neoplasms. After endoscopic treatment, surveillance of the bladder must also be maintained with cystoscopy. Evaluation of the upper tracts for new or recurrent tumors must be maintained with other techniques. Ureteroscopy is the most sensitive technique to evaluate the upper tract and should be used routinely in follow-up surveillance. Grossman *et al*. reported one patient with diffuse upper tract TCC detected by ureteroscopy and confirmed on nephroureterectomy who had a normal excretory urogram [69]. Keeley *et al*. found that the sensitivity of retrograde ureteropyelography for detecting recurrent upper tract tumors was only 25% [85]. In another series, urinalysis, voided cytology, retrograde ureteropyelography, and ureteroscopic biopsy were compared in patients with ureteroscopically visualized and treated tumors [94]. None of those tests could accurately and routinely detect tumors. There was a high specificity of bladder urine cytology and urinalysis, which do support their use. If they are abnormal, earlier endoscopy should be undertaken. At this time, the role of FISH in detecting recurrent upper tract tumors appears to be minimal.

Various surveillance protocols have been proposed. Some authors recommend excretory urography or retrograde ureteropyelography at intervals of 3–6 months, with ureteroscopy used only when specifically indicated. However, the greater sensitivity of direct endoscopic inspection must be recommended as a major technique for surveillance. Ureteroscopy is continued at intervals of 3 months until the upper tract is clear, at which time the patient is examined ureteroscopically at 6-month intervals. Cystoscopy and cytology with urinalysis are continued at intervals of 3 months during the first 2 years (Table 41.7). Evaluation of the contralateral collecting system with retrograde pyelography should be performed at least yearly and possibly at 6-month intervals.

Complications

Complications can occur with any ureteroscopic procedure but there are some that appear to be specific to ureteroscopic tumor treatment. Many of the problems related to dilation of the UPJ can be avoided by the use of small diameter rigid and flexible ureteroscopes. Electroresection is rarely used, and therefore the complications inherent in that procedure are uncommon. With any of the techniques commonly used, electrocoagulation, laser coagulation or resection with a Nd:YAG or Ho:YAG laser, there remains a risk of stricture from scarring of the ureter or an infundibulum. A review of complications from published series of ureteroscopic treatment of upper tract tumors indicates a ureteral stricture rate of 13%, which is considerably higher than the rate of less than 1% seen for stone treatment [95]. This may be an inherent risk of ureteroscopic tumor treatment, since the ureter itself is specifically traumatized with the treatment of the neoplasm. In comparison, damage to the ureteral wall during stone treatment is diligently avoided (Table 41.8).

Perforation remains a strong theoretical risk. However, reported series have not shown any strong propensity toward intraluminal tumor dissemination, implantation, extraluminal tumor, or tumor extension. As noted above, there is no increased risk of tumor recurrence with ureteroscopic biopsy [40].

Adjuvant therapy

Adjuvant chemotherapy or immunotherapy is an attractive option in the treatment of upper tract TCC, particularly in view of the high recurrence rate. The safety and potential advantages of adjuvant therapy have been demonstrated in several short series but this treatment has no proven role.

Bacillus Calmette-Guérin (BCG) has been used as topical therapy in the upper tract with positive cytology. Sharpe *et al*. administered BCG through retrograde

Table 41.8 Strictures after ureteroscopic treatment of upper urinary tract transitional cell carcinoma.

ureteral catheters in patients with abnormal lateralizing cytology [96]. Seventeen renal units were treated in 11 patients and the urinary cytologic specimen normalized in eight of the 11 patients with a median follow-up of 36 months. One patient experienced fever and required antituberculosis therapy, but there were no other complications in the group. Schoenberg *et al*. also reported percutaneous instillation of BCG. One of nine patients developed fever [97]. Belman *et al.* reported that four of 32 patients treated with BCG after percutaneous tumor resection developed asymptomatic renal granulomatosis and three had fever that required treatment [98].

Mitomycin C has also been used in the upper tract and has been found to be tolerated by patients. Eastman and Huffman reported seven patients with mitomycin C instilled in the intrarenal collecting system through a simple J-ureteral catheter or a percutaneous nephrostomy tube after endoscopic resection of upper tract tumors [99]. No systemic side effects were noted, and there was no evidence of disease progression in six patients. Keeley and Bagley similarly found that mitomycin C could be administered without serious sequelae [100]. They found that higher risk grade II tumors that were either larger or multifocal and treated with adjuvant mitomycin C recurred at the same rate as smaller solitary grade II lesions not treated with mitomycin C after ureteroscopic treatment.

Gupta *et al.* have used half-dose BCG and interferon instilled directly into the ureter via a ureteral catheter in weekly doses over 6 weeks [101]. They noted clearance in those patients with isolated upper tract positive cytology.

Thus, adjuvant therapy with either BCG or mitomycin C has been shown to be feasible, but efficacy has not been demonstrated.

Cost of treatment

The application and the need for endoscopic resection and surveillance for upper tract tumors have raised concerns regarding the costs of this management. Pak *et al.* examined the direct costs of renal-sparing conservative measures versus nephroureterectomy and subsequent chronic kidney disease or endstage renal disease [102]. In a cohort of 57 patients with a minimum follow-up of 2 years, renal preservation was 81% with cancer-specific survival of 94.7%. On examination of Medicare payments, even the worst case scenario of a solitary kidney with recurrences at each follow-up for 5 years versus nephroureterectomy and dialysis for the same period would save over US$250 000. This same savings could alleviate the expense of five cadaveric renal transplantations.

Familial neoplasm of the upper urinary tract

Hereditary nonpolyposis colorectal cancer syndrome (HNPCC) is an autosomal dominant disorder which is characterized by germline mutations in DNA mismatch repair genes. The syndrome is associated with multiple colorectal neoplasms and extracolonic tumors, especially of the endometrium, but also of the breast, ovary, and upper urinary tract. Bladder cancer does not appear to be increased in affected family members [103].

The mutations found in HNPCC can be detected as microsatellite instability (MSI) in some DNA sequences or alternatively as the loss of immunostaining for the specific proteins. In one series, analysis showed MSI in 31.3% of consecutive upper urothelial tract carcinomas, the highest frequency reported in any type of tumor [104]. There is an increased risk of developing TCC of the renal pelvis or ureter in patients with HNPCC. However, there is no increased risk of bladder cancer or renal cell carcinoma. Therefore, there is interest in screening of these patients for upper tract urothelial lesions. Excretory urography has been suggested as one option and voided cytology and urinalysis are other options. Reports on screening for recurrences after endoscopic treatment support the value of these studies but also note the lack of sensitivity [105].

In affected members, upper tract neoplasms tend to occur at an earlier age and can be bilateral. These lesions can be treated as other upper tract tumors have been. A conservative, endoscopic approach even in patients with two functioning kidneys should be considered because of the increased risk of developing additional lesions. Successful ureteroscopic treatment of bilateral ureteral tumors, renal pelvic neoplasms, and ureteral lesions in affected patients as young as 42 years have been reported. Postoperative screening in those patients has been by the routine endoscopic surveillance protocol noted above [106]. The presence of upper urinary tract tumors in patients with a history of colon cancer, especially with other associated primary neoplasms at

potentially involved sites, including the breast, ovaries, and pancreas, should be considered for screening for HNPCC. Conservative treatment should be considered as first-line therapy.

Benign neoplasms

Benign urothelial neoplasms are rare in the renal pelvis and ureter. Many individual cases or short series have been reported and include fibroepithelial polyps, inverted papillomas, and hemangiomas, as well as the more commonly noted ureteritis cystica.

Fibroepithelial polyps typically appear in young patients as a smooth pedunculated mass in the upper urinary tract, often occurring at the UPJ. Historically, these lesions have been treated by open surgical resection. However, the availability of small ureteroscopes and appropriate biopsy or resection devices, such as used for TCCs, has permitted ureteroscopic diagnosis and treatment [107–109]. Follow-up after treatment is required only to confirm healing without significant stricture.

Inverted papillomas have also been considered benign lesions, although the association with TCC and the difficult histopathologic diagnosis has raised concern. The most common presentation is with hematuria [110]. However, they can also cause obstruction with hydronephrosis. Endoscopically, they appear as a smooth mucosal-based neoplasm. Often, there is a relatively narrow base encompassing less than one-quarter circumference of the ureter. The lesions lack the papillary configuration of low-grade TCC, but can be confused with a higher grade lesion. Endoscopic biopsy is a crucial diagnostic study. It is particularly helpful to excise the entire lesion [111–113]. Follow-up should be maintained both to confirm the patency of the urinary tract and because of the possible association with new TCC. These neoplasms can be treated adequately ureteroscopically.

Totally endoscopic management of upper tract transitional cell carcinoma

Ureteroscopy constitutes an important facet in the totally endoscopic management of upper urinary tract TCC. Suspicious lesions are visualized and biopsied ureteroscopically and many lesions can be treated ureteroscopically. Larger lesions, which cannot be treated ureteroscopically, may be treated more efficiently by percutaneous nephroscopy with laser or electrosurgical resection. Those that are too large or too extensive, or higher grade, or found through surveillance to be uncontrolled endoscopically, require nephroureterectomy, usually with laparoscopic nephroureterectomy. Surveillance is maintained with cystoscopy and ureteroscopy [114, 115]. Upper urinary tract TCC, therefore, can be managed almost entirely endoscopically in the majority of patients (Table 41.9).

Table 41.9 Totally endoscopic management of upper urinary tract transitional cell carcinoma.

Diagnosis: ureteroscopy
Treatment: ureteroscopic or percutaneous nephrolithotomy
Nephroureterectomy: laparoscopy
Surveillance: ureteroscopy

CHAPTER 42
Retrograde Ureteroscopic Endopyelotomy for Ureteropelvic Junction Obstruction

Ugur Boylu & Raju Thomas
Department of Urology, Tulane University School of Medicine, New Orleans, LA, USA

Introduction

Advances in technology and instrumentation have changed the practice of urology, especially over the past decade. One of the areas of major impact has been the treatment of ureteropelvic junction obstruction (UPJO), which is defined as an anatomic or functional impedance of urine flow from the renal pelvis into the ureter [1] (Figure 42.1). This condition can be congenital or acquired, the congenital form being the more common. UPJO, although relatively uncommon, warrants prompt attention to alleviate symptoms and prevent deterioration of renal function. Several factors can play roles in the development of UPJO, including intrinsic aperistalsis of the involved ureteral segment, crossing aberrant vessels causing direct compression of the ureter, renal stone disease, and previous surgical or endourologic manipulation.

The advent of smaller-caliber endoscopes [2], and development of laparoscopic reconstructive techniques, laser technology, and robotics have diversified the treatment options for this condition.

Although the efficacy, and decreased morbidity, hospital stay, and need for analgesia with endopyelotomy have been clearly demonstrated, several issues have still not been completely resolved. Should patients be managed initially by ureteroscopy? What are the exclusion criteria for these endoscopic procedures? What are the relative merits of antegrade versus retrograde approaches? In the era of minimally invasive laparoscopy and robotic-assisted surgery, is there still a role for endopyelotomy?

In this chapter we discuss the technique and results at our institution for retrograde ureteroscopic endopyelotomy for the treatment of UPJO.

History

Several reconstructive procedures have been described for the management of UPJO since Trendelenburg's first description of such a procedure in 1886. Open surgical correction was the only mode of treatment for this condition before the introduction of endoscopic and laparoscopic techniques, and has been considered the gold standard of treatment for this condition, with success rates over 90% [3]. However, associated morbidity is not unusual with open surgery; specifically, there is fistula formation in 2.6% of patients, stricture of the UPJ in 2.4%, and the need for nephrectomy in 3.2% [4].

The present-day endourologic approach to the management of UPJO can be traced back to the original descriptions of Albarran, Keyes, and Davis. Albarran did the first endosurgical repair of the UPJO in 1903, which actually described a ureterotome externe [5]. Keyes performed a similar procedure successfully in 1915 [6]. Both the antegrade and retrograde endopyelotomy follow the concept of Davis's intubated ureterotomy, first described by Davis in 1943. In 1985, Bagley *et al*. reported a combined percutaneous and flexible ureteroscopic approach for the management of an obliterated UPJ [7]. Wickham and Kellet described the first ureteroscopic pyelolysis of the UPJ in 1983 [8], and this was repeated by Inglis and Tolley in 1986 [9]. Thomas

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Figure 42.1 Intravenous pyelogram of a right ureteropelvic junction obstruction (arrow).

et al. described their experience of ureteroscopic endopyelotomy in which prestenting was performed to facilitate ureteroscopy in 1996 [10]. A single-setting, one-stage procedure was subsequently described by Soroush and Bagley in 1998 [11].

There are now multiple different options for the treatment of UPJO, including antegrade nephroscopic endopyelotomy, retrograde ureteroscopic endopyelotomy, Acucise™ (Applied Medical, Rancho Santa Margarita, CA, USA), and laparoscopic and robot-assisted pyeloplasty, as well as the traditional open surgical pyeloplasty [12]. As mentioned above, open surgical dismembered pyeloplasty has been considered the gold standard for the treatment of UPJO, with success rates of over 90%. However, many institutions now consider endopyelotomy a possible first-line therapy option for the treatment of this condition [13–16].

Currently, a retrograde endopyelotomy can be performed in three ways: (1) using a rigid ureteroscope and a cold-knife, electrocautery, or holmium laser incision; (2) using a flexible ureteroscope and electrocautery or laser incision; and (3) in rare select cases, using a balloon with a cutting wire (Acucise) [15]. Additionally, an emerging technique of dilation and cold-cut incision with a peripheral cutting balloon, which was originally designed for angioplasty, is currently being investigated [17–19].

Different series have reported success rates for retrograde ureteroscopic endopyelotomy to be in the range of 73–90% [10, 11, 20–24]. As compared with other treatment options, ureteroscopic retrograde endopyelotomy is less invasive, requires less operating room time, enables the procedure to be performed on an outpatient basis or with a very short hospital stay, and is associated with a shorter convalescence period [1, 13, 25–29]. Also, the initial report of ureteral stricture formation because of thermal injury from transmission of the electrocautery current has been eliminated with the use of insulated ureteroresectoscopes and holmium laser fibers [30].

Patient selection and preoperative preparation

The presumptive clinical diagnosis of UPJO can be evaluated and/or confirmed with a renal ultrasound, intravenous pyelogram (IVP), diuretic renal scan, retrograde pyelogram, computed tomography (CT) scan, Whitaker test, or with a combination of these, as is clinically indicated. The renal scan, besides aiding in the diagnosis of a UPJO, gives a quantitative differential renal function, which can be used to choose the best treatment option and, further, to allow for follow-up evaluation of the renal function.

Either a spiral CT angiography or an endoluminal ultrasound is highly recommended to assess for the presence of an aberrant crossing vessel. The UPJ area can also be evaluated ureteroscopically for the presence of pulsations before performing the endopyelotomy incision.

Although ureteroscopic retrograde endopyelotomy is applicable to most patients with UPJO, there are some absolute and relative exclusion criteria. Among the absolute contraindications are patients with active infection and bleeding diathesis.

Patients with concurrent renal calculi and UPJO, and patients with a nephrostomy tube in place, should be treated with an antegrade approach so that both the renal stone and the UPJO can be managed in a one-stage procedure. Patients with a relatively long length of obstruction, usually greater than 2 cm, are best managed either with open surgical, laparoscopic, or robotic-assisted techniques. Patients with ipsilateral differential renal function of less than 20% and severely decreased parenchymal thickness can be given a trial of drainage and re-evaluation [15] or should be offered a laparoscopic simple nephrectomy for a poorly functioning or nonfunctioning kidney. Patients with massive hydronephrosis should be treated with dismembered pyeloplasty, either open surgical, laparoscopic, or robot assisted, because of the need for trimming and reduction of the redundant renal pelvis. Controversy exists

with regard to patients with high insertion of the UPJ and crossing vessels. Although once considered a contraindication because of poor results, published series report that the type of ureteral insertion has no significant impact on the outcome of endopyelotomy [24], and that patients with crossing vessels had long-term success with retrograde endopyelotomy [14]. We routinely perform laparoscopic robotic-assisted pyeloplasty in both cases with a high insertion UPJO or a known crossing vessel [12]. Lastly, patients with known intractable stent intolerance should be considered candidates either for an antegrade endopyelotomy or an open pyeloplasty with a nephrostomy tube, and not for ureteroscopic endopyelotomy.

Once the surgeon and patient have decided on the retrograde approach for management of a UPJO, an indwelling ureteral stent is usually placed to drain the obstructed renal unit for 1–2 weeks. This procedure not only drains the obstructed renal unit, but also stabilizes its renal function, dilates and straightens the UPJ, and facilitates subsequent passage of the ureteroscope into the renal pelvis. Above all, preoperative placement of the stent allows evaluation of any degree of stent intolerance and identifies improvement of renal function after drainage.

Table 42.1 Required instrumentation.

Holmium laser ureteroscopic endopyelotomy
7.5F rigid and/or flexible ureteroscope
200- or 365-µm holmium laser fiber at the following settings: • 1.5–2.5 J • 10–15 Hz
Super-stiff guidewire (0.038-inch)
Single-action pump system (Microvasive, Watertown, MA, USA)
Endopyelotomy stent (Microvasive or Applied Medical, Rancho Santa Margarita, CA, USA)
Routine cystoscopy and fluoroscopy set-up
Ureteroscopic endopyelotomy with electrocautery
11.5F ureteroresectoscope (Karl Storz, Culver City, CA, USA; Richard Wolf, Rosemont, IL, USA) (Figure 42.2): • Insulated electrocautery knife • Cold knife • Electrocautery attachments
Single-action pumping system (Microvasive)
Super-stiff guidewire (0.038-inch)
5F open-ended catheter
Endopyelotomy stent (Microvasive or Applied Medical)
Routine cystoscopy and fluoroscopy set-up

Informed consent

On the day of the scheduled endopyelotomy, any final questions are answered and an informed consent is obtained after explaining and discussing with the patient the expected outcomes and benefits of the procedure (e.g. improved renal drainage, preservation of renal function, diminished risk of calculus and infection, minimally invasive procedure), its associated risks or complications (bleeding, infection, possibility of conversion to open surgery, recurrence, etc.), and the other minimally invasive treatment options available. Patients are informed that postoperative evaluations may show some residual caliectasis, especially in those with longstanding UPJO.

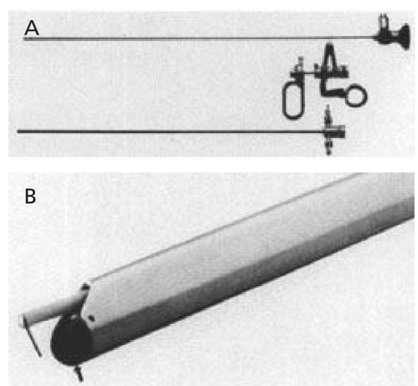

Figure 42.2 (A) 11.5F Ureteroresectoscope with insulated tip. (B) Close-up view of ureteroresectoscope shows insulated cutting electrode in place (arrow).

Step-by-step operative technique

The required instrumentation is listed in Table 42.1.

After either a general or a spinal anesthesia, the patient is placed in the lithotomy position. Caution is taken so that all pressure points are well cushioned, and antiembolic stockings are used in high-risk patients.

With the use of a cystoscope, and under fluoroscopic guidance, a retrograde pyelogram is performed to confirm the length of the UPJO segment, and subsequently a super-stiff guidewire is passed and coiled into the renal pelvis. If the patient had a previously placed indwelling ureteral stent, it is removed and used to pass the guidewire prior to removing the stent. A retrograde pyelogram can assess any resolution of hydronephrosis and can be used as a prognostic indicator.

The next step varies depending on whether the endopyelotomy is done with electrocautery through a ureteroresectoscope or whether a holmium laser is used through a rigid, semi-rigid, or flexible ureteroscope.

Holmium:YAG laser ureteroscopic endopyelotomy

A 7.5F self-dilating rigid, semi-rigid, or flexible ureteroscope is passed alongside the super-stiff guidewire using generally accepted ureteroscopic techniques. A balloon dilator can be passed over the guidewire and the ureteral orifice dilated in case of difficulty advancing the ureteroscope within the ureter. If necessary, another guidewire can be passed through the ureteroscope and the narrow area subsequently balloon dilated.

Once at the UPJ, this is first inspected for the presence of any transmitted pulsations. A 365-μm holmium laser fiber, when using a rigid or semi-rigid ureteroscope, or a 200-μm fiber in the case of a flexible ureteroscope, is passed through the working channel of the ureteroscope. At a setting of 1.5–2.5 J and a frequency of 10–15 Hz, the UPJ is incised under direct vision either laterally or posterolaterally to avoid the risk of injuring any unsuspected crossing vessel. The incision is carried on until periureteral fat is seen and the UPJ is wide enough to permit easy passage of the ureteroscope into the renal pelvis (Figure 42.3).

After hemostasis of any venous bleeding is performed, the laser fiber and ureteroscope are removed. The UPJ area is dilated up to 24F using a balloon dilator under fluoroscopic guidance. The concept of balloon dilation of the UPJ is based on Davis's intubated ureterotomy, in which the incised and dilated ureteral fibers regenerate around the ureteral stent over a 6-week period [6] (Figure 42.4).

The balloon dilator is then removed. An endopyelotomy stent is placed under fluoroscopic control, leaving the 14F or 10F end at the UPJ (depending on the stent used) and the 7F end coiled in the bladder (Figure 42.5). Alternatively, an 8F double-J ureteral stent can be left in place. The authors recommend using a ureteral stent one size longer than anticipated to prevent downward migration of the renal coil into the incised UPJ, which may leak into the retroperitoneal space with formation of a urinoma.

An indwelling Foley catheter is placed to drain the bladder for 48 h. This helps to maintain a low pressure in the urinary system and to prevent urinary reflux through the ureteral stent into the incised UPJ, which also may leak into the retroperitoneal space, possibly causing formation of a urinoma.

Ureteroscopic endopyelotomy with electrocautery

A 5F open-ended catheter is passed over the super-stiff wire. The open-ended catheter works as an insulator,

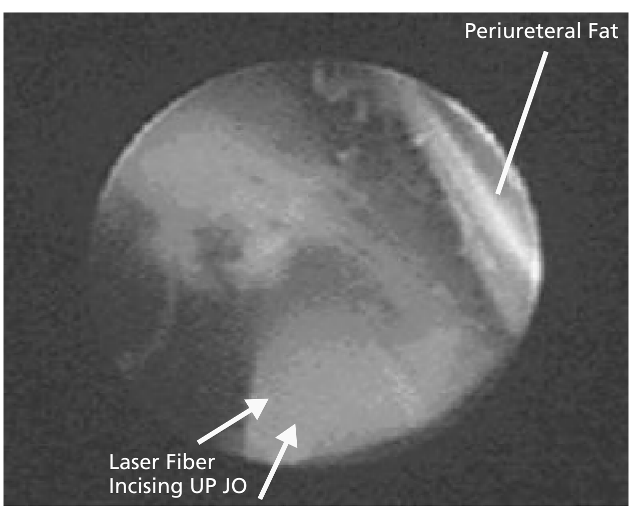

Figure 42.3 Periureteral fat seen after the ureteropelvic junction was incised with a holmium laser. UPJO, ureteropelvic junction obstruction.

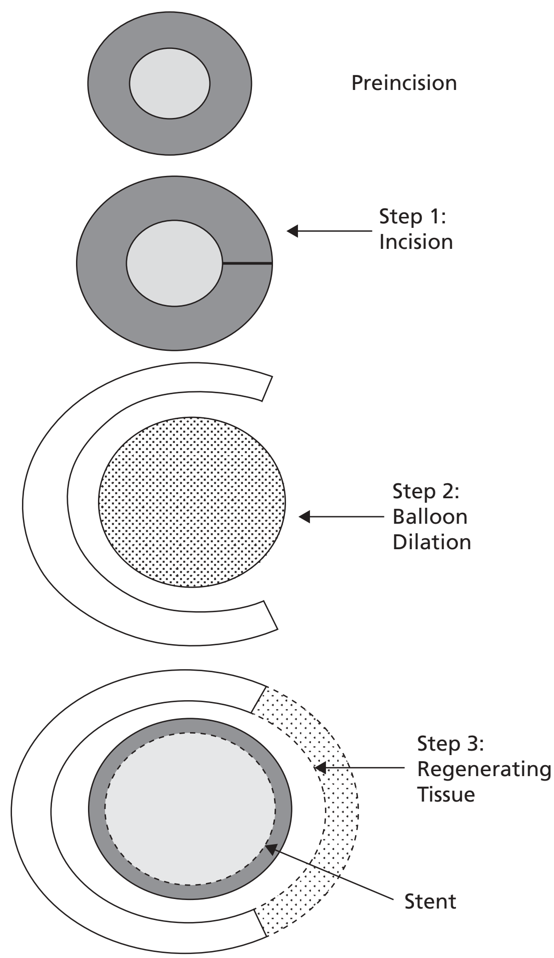

Figure 42.4 Tissue regeneration after incision and balloon dilation.

Figure 42.5 Endopyelotomy indwelling stent in place after ureteropelvic junction obstruction incision.

preventing contact with the electrocautery element, and avoiding transmission of current along the length of the guidewire if contact is made. Also, the open-ended catheter may serve to continuously drain the renal pelvis of the irrigant used during the procedure, once the wire is removed.

The ureteroresectoscope is passed directly alongside the insulated guidewire with the cold knife in place. The electrocautery element is right angled and would impede vision if placed during the insertion of the ureteroresectoscope [1]. If there is difficulty accessing the ureteral orifice or the intramural ureter, a balloon dilator can be passed over the guidewire to dilate the area. If there is resistance advancing the ureteroresectoscope along the ureter proximal to the UPJO, a smaller self-dilating ureteroscope can be passed to passively dilate the ureter and to inspect for the cause of the narrow area. If necessary, another guidewire can be passed through the self-dilating ureteroscope and the narrow area is balloon dilated.

Once at the UPJ, the cold-knife working element is exchanged for the electrocautery element. Either water or 1.5% glycine solution is used as the irrigant during electrocautery for incision.

The UPJ is first inspected for the presence of any transmitted pulsations, and then incised laterally, between 8 and 9 o'clock on the right and between 3 and 4 o'clock on the left. Short and shallow strokes should be performed and aggressive and deep incisions avoided. Any bleeding site is controlled by means of spot electrocoagulation. The incision is carried down until periureteral fat is seen and the ureteroresectoscope enters the renal pelvis with ease.

The ureteroresectoscope and the open-ended catheter are removed. The rest of the subsequent steps, balloon dilation, stenting, and Foley catheter drainage, are the same as described above for the holmium:YAG laser endopyelotomy.

Postoperative care

The vast majority of patients are discharged either the same day or within the first 24 h following the procedure. Oral antibiotics, usually quinolones, are given for 3–5 days; oral antispasmodics and/or oral anticholinergics are given as needed in case of irritative bladder symptoms. The Foley catheter is removed, often by the patient, after 48 h. The ureteral stent is removed cystoscopically in 6 weeks.

Diuretic renal scans or IVP are performed 4 weeks after ureteral stent removal. Patients are followed-up with renal ultrasound or renal scan every 4–6 months during the first year and yearly thereafter or as needed.

Success following endopyelotomy is measured by evaluating improvement of the function and drainage of the involved kidney and alleviation of symptoms. After correction of the obstruction at the UPJ, postoperative radiographic images from an IVP or CT scan often show residual caliectasis resulting from long-standing obstruction and dilation that may not completely resolve.

Results

We analyzed the outcome of 139 consecutive patients who underwent retrograde ureteroscopic endopyelotomy at Tulane University Health Sciences Center between 1989 and 2002. These patients included seven pediatric patients, four solitary kidneys, two horseshoe kidneys, and one ptotic kidney.

The average postoperative hospital stay was less than 24 h. Seventy-nine percent of the patients were discharged home on the same day, and 97% of them within 24 h.

Of the 139 patients 32 (23%) required subsequent procedures to treat recurrence of obstruction, showing an overall long-term success rate for retrograde ureteroscopic endopyelotomy of 77%. Fourteen of these patients (10%) required major open or laparoscopic surgical intervention, including nephrectomies for severe hydronephrosis and nonimprovement in renal

function in three (2%) cases, emergent nephrectomy for severe bleeding in one (0.7%), dismembered pyeloplasties in eight (5.7%), and spiral flap pyeloplasties in two (1.4%).

Eighteen (12.9%) patients required minor procedures, which included cystoscopy and balloon dilation of the UPJ in 13 (9.3%), repeated retrograde endopyelotomy in four (2.8%), and long-term indwelling stent exchange in one (0.7%). There were no ureteral strictures secondary to manipulation in our series.

After analyzing the failures of treatment in this series, two factors were obviously associated with poor results (no improvement of symptoms, drainage, and function after endopyelotomy): (1) a long-standing obstruction with a decrease in ipsilateral renal function of less than 20% of the total renal function; and (2) a severely dilated renal pelvis, which did not improve on drainage with an indwelling ureteral stent..

After evaluation of these results, we conclude that patients with patulous redundant renal pelvis and borderline salvageable renal function should be considered candidates for alternative treatment modalities, such as open or laparoscopic/robotic pyeloplasty or nephrectomy, rather than endopyelotomy.

Complications

Since its initial description by Young in 1912, retrograde ureteroscopy has come a long way and has gained widespread acceptance as an option for the treatment of multiple pyeloureteric conditions. Further advances in technology have lead to the introduction of smaller-caliber ureteroscopes with the capacity to accommodate accessory instruments necessary to perform diagnostic and therapeutic upper urinary tract procedures.

As with ureteroscopy, the complications and adverse events associated with retrograde ureteroscopic manipulation of the ureter have decreased dramatically in the past two decades. Smaller-caliber ureteroscopes, the advent of laser technology, improved paraphernalia, and, above all, experience in the procedures should be given credit. Although these advances have decreased the need for open ureteral surgery, iatrogenic injury can still occur with the endoscopic technique. Possible iatrogenic complications of ureteroscopy include ureteral perforation, stricture, false passage, ureteral avulsion, bleeding from the ureteral mucosa or adjacent structures, infection, and sepsis. Multiple studies have reported the overall complication rate of ureteroscopy to fluctuate between 1% and 15% [31–33].

The reported incidence of pain, fever, false passage, and urinary tract infection are 5.5%, 1.4%, 0.4%, and 1.6%, respectively, in one large ureteroscopy series [34].

Other complications associated with incision of the UPJ can include bleeding from adjacent aberrant vessels, stent migration through the UPJ incision, and UPJO recurrence. Significant bleeding requiring emergent nephrectomy is another possible complication that justifies the need for vascular or three-dimensional (3D) radiographic studies to identify aberrant vessels. The use of a complete lateral incision at the UPJ helps to prevent injuries to those vessels.

Minor complications of retrograde ureteroscopic endopyelotomy include proximal stent migration, stent intolerance, minor bleeding, and urinary tract infection after manipulation. Most of these complications are alleviated after removal of indwelling ureteral stents. The routine use of antispasmodic and anesthetic drugs after surgery improves tolerance to the stent and decreases complaints from the patient.

Comparison of treatment approaches and conclusions

Multiple endourologic and open surgical techniques are now available for the treatment of UPJO. The choice of technique relies primarily on the urologist's experience with each procedure, available equipment, and the need to perform another concomitant procedure.

Antegrade endopyelotomy requires expertise in percutaneous renal surgery, with detailed knowledge of the intrarenal anatomy and adequate experience in "real-time" 2D fluoroscopic imaging. This is the preferred technique when treating concomitant intrarenal calculi, but it is also associated with a larger potential for complications and morbidity. The occurrence of pneumothorax, adjacent organ trauma (i.e. bowel, spleen, liver), and hydrothorax are possibilities that need to be explained to the patient prior to the surgery. Antegrade and retrograde endopyelotomy share the potential for hemorrhage from injury to aberrant crossing vessels; however, antegrade access may also be associated with hemorrhage from the percutaneous renal tract and with a higher risk of infection owing to external urinary drainage through the percutaneous nephrostomy tube.

Acucise retrograde endopyelotomy relies on fluoroscopic imaging and not on direct visualization during cutting of the UPJ. High-quality fluoroscopic imaging is critical for optimal electrode placement. Short-term success rates of this procedure have been comparable to those obtained with retrograde ureteroscopic endopyelotomy and range from 66% to 84% [35]. Extreme caution should be exercised when using this technique in the presence of aberrant crossing vessels. Preoperative CT scan with angiographic phase and 3D reconstruction has been shown to be adequate to collect information regarding periureteral vasculature at the level of the obstruction [36]. Incision at the lateral position of the UPJ should minimize the risk of vascular injury while performing this procedure. Use of this technique has

dramatically decreased because of lower success rates with long-term follow-up.

Multiple different indwelling stents can be used to maintain patency of the UPJ after an endopyelotomy. At our institution we use an 8F double-J ureteral stent with postoperative results similar to those obtained with endopyelotomy stents. It is always important to use an indwelling stent one size longer than anticipated in order to avoid downward migration of the stent that could compromise endopyelotomy healing.

It is our belief that retrograde ureteroscopic endopyelotomy provides a safe and adequate first-line treatment for patients suffering from UPJO. With the advent of smaller scopes and devices, this technique has evolved to include larger children as possible patients. Adherence to strict endourologic principles and direct visualization makes retrograde ureteroscopic endopyelotomy a safe and effective treatment modality. Furthermore, this procedure has a short learning curve and can be performed in almost all general hospitals where ureteroscopy is performed.

Lastly, this procedure should always be part of a urologist's treatment armamentarium, because patients who have failed laparoscopic, robotic, or open surgical pyeloplasty can be managed with ureteroscopic retrograde endopyelotomy.

CHAPTER 43

Mid-Ureteral Obstruction

Mrinal Dhar & Michael Grasso

Department of Urology, New York Medical College, Westchester Medical Center, Valhalla, NY, USA

Introduction

Advances in both diagnostic and therapeutic endoscopy have resulted in a paradigm shift away from open surgery to minimally invasive management of ureteral obstruction. The causes of ureteral obstruction are numerous, often occurring at any location along the length of the ureter. This chapter focuses primarily on the etiology, evaluation, indications for intervention, as well as the endourologic and laparoscopic management of obstructing lesions in the middle third of the ureter.

Etiology

A proper understanding of ureteral anatomy is essential (see also Chapter 33). To facilitate ureteral description, the ureter can be divided into upper, middle, and lower segments. The middle third of the ureter comprises the segment that crosses anterior to the sacrum. It is also the segment that passes over the iliac vessels. Mid-ureteral obstruction is a common presentation to endourologists. Ureteral obstruction can be characterized as inflammatory, malignant, or congenital, e.g. tuberculosis and schistosomiasis cause significant ureteral inflammation during the active infection, with subsequent fibrosis commonly involving the distal half of the ureter [1, 2]. Other benign causes of ureteral strictures include prior radiation therapy, inflammatory abdominal aortic aneurysm, endometriosis, and regional trauma, including iatrogenic injury from previous abdominal or pelvic surgery [3, 4].

The causes of ureteral obstruction can also be divided into extrinsic (compressive), intrinsic (involving the ureteral wall), and intraluminal. Examples of extrinsic causes of obstruction include retroperitoneal fibrosis, pelvic lipomatosis, obstetric and gynecologic causes (pregnancy, tubo-ovarian abscess, retroperitoneal endometriosis, ovarian mass lesions), and vascular causes (abdominal aortic and iliac artery aneurysms, vascular graft compression, gonadal vein thrombophlebitis, circumcaval ureter). Intrinsic causes include fibrosis and stricture, ureteral wall endometrioma, and submucosal foreign body with associated granulomatous reaction (e.g. submucosal stone; Figure 43.1). Examples of intraluminal causes of obstruction include papillary urothelial carcinoma (Figure 43.2), an impacted ureteral calculus, sloughed papilla due to papillary necrosis, and inflammatory mass lesions, which can be either fungal or bacterial in origin.

The basic tenet with regard to treating an intraluminal obstruction is to remove the lesion and allow the local reaction to resolve over time. Persistent obstruction thereafter often reflects an intrinsic ureteral wall process, the most common of which is ureteral wall fibrosis or stricture. Other causes of intrinsic ureteral wall obstruction are listed in Table 43.1. Malignant causes such as urothelial carcinoma can appear on contrast-based imaging as a radiolucent filling defect within the lumen with the classic goblet or Bergman's sign. The majority of upper urinary tract urothelial tumors are papillary, like those encountered in the bladder, with a significant percentage of the higher grade lesions having an

intrinsic, invasive component involving the ureteral wall (see Video 43.1A). Secondary or metastatic tumors (e.g. cervical, prostate, ovarian, breast, and colon) can involve the ureter and cause high-grade obstruction. As opposed to ureteral strictures that are the product of inflammatory, infectious, or iatrogenic causes, those associated with or the product of treatment for a malignancy (i.e. radiation fibrosis) are the most challenging to treat.

The incidence of ureteral strictures in the general population is unknown, but the presence and treatment of ureteral calculi are significant risk factors. Those patients with long-standing ureteral obstruction from an impacted ureteral calculus are at high risk for subsequent stricture after successful lithotripsy. Roberts *et al*. reviewed 21 patients with impacted ureteral stones and found that stones impacted for greater than 2 months were associated with a 24% incidence of stricture formation [5]. Endoscopic management of ureteral calculi may also lead to stricture formation. Ureteroscopic lithotripsy's origins began with pioneering work in the early 1980s. These centers employed large-caliber (>12F) rigid ureteroscopes, often requiring significant dilation for access, combined with traumatic lithotrites like electrohydraulic probes. The risk of perforation and subsequent stricture with these early techniques was an unacceptably high 10%. Advances in materials and endoscope design led to smaller and flexible endoscopes with improved optics. The addition of the small diameter, actively deflectable, flexible ureteroscope and laser lithotrite significantly decreased tissue trauma. For these reasons, the incidence of ureteral stricture formation from ureteroscopic instrumentation has dramatically decreased to less than 1% [6, 7]. Dretler and Young were the first to describe the entity of a "stone granuloma" as embedded particles of calcium oxalate associated with macrophages and foreign body giant cells in the wall of the ureter [8]. This is a possible, although rare, complication of ureteroscopy where partial ureteral disruption during ureteral stone fragmentation results in stone material being embedded in the ureteral wall, causing surrounding fibrosis and ureteral obstruction (see Videos 43.2A and B).

Evaluation

The evaluation of an obstructed upper urinary tract often begins with sonography. Hydronephrosis and proximal ureteral dilation are often the limits of gray-scale sonographic imaging. Color Doppler enhancement is useful in defining renal arterial perfusion, arterial resistive indices, and also the presence of ureteral flow jets in the bladder. Computed tomographic (CT) urography is the most common next imaging study. Three-phase CT imaging, with noncontrast, perfusion, and then drainage phases is often essential in defining the location and etiology of ureteral obstruction. Delayed CT imaging is useful in differentiating intrinsic ureteral lesions from those caused by external compression. It is essential to perform sufficiently delayed imaging to visualize the entire ureter, in an attempt to clarify the exact location and cause of the obstruction. When CT imaging does not clearly define the cause of obstruction, either from poor excretion or impaired renal function from obstruction, then direct instillation in either an antegrade or retrograde fashion (i.e. retrograde ureteropyelography) is particularly useful in defining the length, location, and nature of ureteral obstruction.

If the mid-ureteral obstruction has been chronic in nature and there is evidence of poor renal function of the ipsilateral kidney on CT, then a nuclear medicine renogram (e.g. MAG3) should be performed to evaluate differential function, as this may affect treatment options. Endourologic therapies generally require marginal reversible renal function of the ipsilateral kidney in order to obtain reasonable ureteral patency rates with endoscopic intervention [9]. It is believed that urine flow through the incised or repaired segment of ureter is required in order to maintain patency. A diuretic can be administered during the renogram to assess for functional obstruction as well, and is particularly useful during surveillance post surgical intervention.

Ureteroscopy is commonly performed to define the nature and location of ureteral obstruction. Endoscopic biopsy is commonly performed when a malignant etiology is being entertained (see Video 43.1B and C). Endoluminal ultrasound, ultrasound imaging from within the ureter with small-caliber high frequency probes, can be employed to direct therapy and characterize a stricture [10]. The advantage of endoluminal ultrasound is particularly evident during endoureterotomy where it can be used by the surgeon to obtain realtime images of surrounding structures, directing the incision away from adjacent vasculature. Intraluminal sonography has also been useful in defining hidden and submucosal calculi, which can cause severe granulomatous local reaction with resultant ureteral fibrosis [11]. Differentiating ureteral edema and inflammatory changes from fibrosis and ureteral scarring can significantly change treatment. When the endoscopic appearance cannot differentiate an obstructing lesion, specialized imaging, including intraluminal sonography, is often useful in directing treatment.

Indications and contraindications for intervention

Mid-ureteral obstruction can reflect many disease states. It is important to differentiate lesions preoperatively to obtain the best surgical outcome. Improving ureteral drainage with surgical intervention can be achieved with a variety of techniques. There are, however, general principles on how and when to intervene surgically. For patients who present with urosepsis and evidence of ureteral obstruction, prompt decompression of the obstructed renal unit should be performed, either by retrograde ureteral stent insertion or percutaneous drainage of the pyelocalyceal system. Definitive management of the mid-ureteral obstruction should then be deferred until the patient recovers clinically from the acute septic episode, the urine culture normalizes post antibiotic therapy, and the inflammatory reaction noted with the acute infectious process subsides.

General contraindications to endourologic intervention are identical to those noted with open surgical intervention employed for ureteral stricture disease (e.g. uncorrectable bleeding diathesis, etc.) Relative contraindications for ureteroscopic incision, for example, include active urinary tract infection versus bacterial colonization, long, dense ureteral strictures, and poor ipsilateral renal function. For patients with long strictures, open or laparoscopic surgical intervention is often superior as endourologic management of strictures greater than 2 cm in length is associated with high recurrence rates.

Endourologic options for intervention

Minimally invasive endourologic interventions are commonly employed once a ureteral obstruction is defined. Balloon dilation and ureteral stenting are employed ubiquitously for lesions collectively termed "ureteral strictures." The relatively high success of these interventions underscores the likelihood that many of these obstructing lesions are inflammatory and most benefit from minor interventions to help facilitate healing. True strictures, a white circular band of scar tissue without lining mucosa, require definitive intervention by either ureteroscopic incision or laparoscopic reconstruction employing viable tissue for repair akin to the historic open surgical repair.

Ureteral stent placement

Commonly, ureteral obstruction can be acutely managed with ureteral stent placement, particularly those secondary to intrinsic ureteral lesions. Extrinsic ureteral obstruction can also be addressed acutely with a firm, larger diameter stent. Percutaneous nephrostomy drainage can also be employed to obtain proximal drainage, especially when retrograde stenting is unsuccessful or inadequate. Chronic stenting, requiring periodic stent changes, is reserved for patients who are deemed poor surgical candidates for definitive repair, those with an overall poor prognosis, or when definitive intervention is deemed high risk. Chronic stenting in the setting of extrinsic ureteral obstruction may, however, lead to slow deterioration in renal function, since adequate drainage may be only temporary [12, 13]. Placement of two large diameter adjacent stents to maintain ureteral patency when a single standard stent has not provide adequate drainage is useful in patients with dense, compressive retroperitoneal fibrosis.

Retrograde ureteral balloon dilation

Retrograde ureteral balloon dilation of an obstructing lesion is commonly performed. With the application of angiographic dilation balloons for this purpose in the early 1980s, the technique of balloon dilation and temporary ureteral stenting became an accepted mode of treatment for ureteral obstruction. Success with balloon dilation varies, based in large part on the underlying etiology of the ureteral obstruction: inflammatory lesions respond well, while long fibrotic segments often require repetitive sessions before ultimately undergoing another definitive treatment.

Indications to intervene with retrograde balloon dilation of a ureteral lesion include functionally significant obstruction where access across the ureteral segment can be obtained using transurethral techniques. The procedure begins with retrograde contrast-based imaging. A pyelogram is performed fluoroscopically to help delineate the site and length of the stricture. Various guidewires, some hydrophilic coated, are employed with a 5F braided ureteral catheter under fluoroscopic guidance to traverse the obstructed segment. This is usually accomplished by placing the open-ended catheter up to the level of the obstruction, and through which the guidewire is directed to gain proximal access. Once access has been obtained proximal to the stricture, the ureteral catheter can be advanced over the guidewire through the obstructed segment. The guidewire can then be exchanged with the catheter for a stiffer Amplatz variety if the ureter requires straightening, for example. The ureteral access catheter is then exchanged over the guidewire for a 4-cm long, 5–8-mm balloon dilation catheter, positioned under fluoroscopy across the ureteral segment using radio-opaque markers as guides (Figure 43.3A). Balloon inflation employing radio-opaque contrast is then performed (Figure 43.3B). A ureteral stent is then inserted over the guidewire with its position verified fluoroscopically. Follow-up imaging is performed 4–6 weeks following stent removal to assess for adequate drainage.

Occasionally, obtaining guidewire access beyond the stricture under fluoroscopic guidance as described above is unsuccessful. In such cases, passage of a guidewire under direct visualization can be accomplished ureteroscopically. The importance of diagnostic ureteroscopy in this setting cannot be overstated. Once guidewire access is obtained in this fashion, the ureteroscope is then withdrawn and the procedure is continued as described previously.

Percutaneous nephrostomy and antegrade balloon dilation

There are times when retrograde access across an obstructed ureteral segment is unsuccessful and thus not feasible. In these cases, antegrade intervention to ensure renal drainage and to gain access to the ureter from this approach is essential. The patient is positioned laterally or prone, and under ultrasound guidance, percutaneous guidewire access to the collecting system is obtained. As with retrograde ureteral access, a hydrophilic guidewire is advanced into the pyelocalyceal system under fluoroscopic guidance. A braided angiographic catheter, like the Kumpe catheter, is then advanced over the guidewire and a nephrostogram performed to delineate the collecting system anatomy and identify the site of ureteral obstruction. The steerable angiographic catheter is then employed to direct the hydrophilic guidewire down the ureter under fluoroscopic guidance. The catheter is then advanced over the guidewire and both are manipulated through the obstructed segment. If access through the obstructed ureteral segment is unsuccessful, the nephrostomy tract can be dilated to facilitate antegrade diagnostic ureteroscopy. After the percutaneous tract is dilated to a diameter that will accept the endoscope, the flexible ureteroscope is then advanced over a guidewire in an antegrade fashion to allow direct visualization of the ureter. Small-diameter, 12F balloon dilators can be passed through the working channel of the flexible ureteroscope and facilitate dilation under both visual and fluoroscopic guidance. These small-diameter (12F outer diameter, 3F sheath diameter), low-pressure balloon dilators that can be passed through the flexible ureteroscope are only useful to assist in endoscope access and have little value in definitively treating a dense stricture. Antegrade balloon dilation and ureteral stenting over a

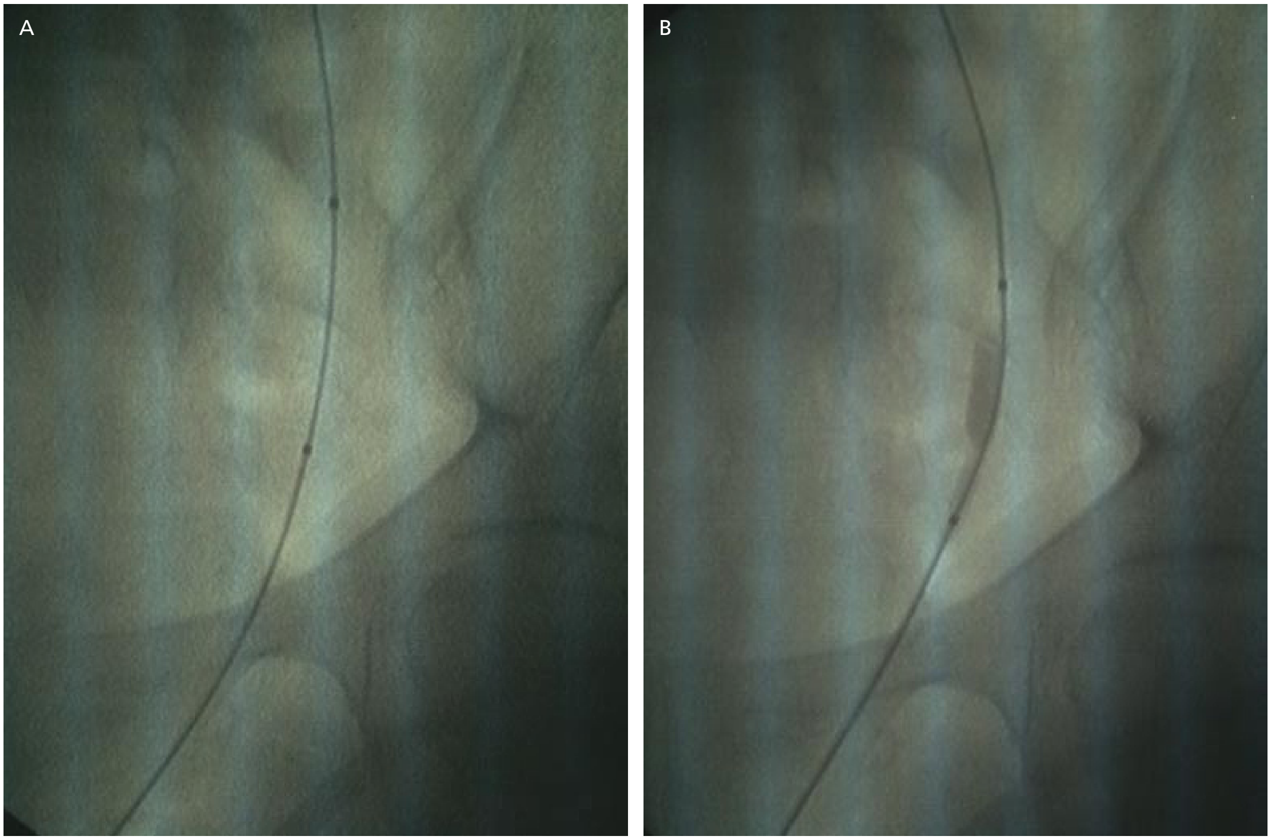

Figure 43.3 (A) Insertion of a balloon dilation ureteral catheter with radio-opaque markers at the level of the ureteral stricture. (B) Inflation of the balloon with contrast demonstrates a "waist" at the level of the stricture.

guidewire is otherwise analogous to the retrograde approach. A nephrostomy tube is then inserted to ensure renal drainage. A follow-up nephrostogram is obtained within the first few days postoperatively to ensure adequate internal drainage before removing the nephrostomy tube. Alternatively, a nephroureteral stent can be inserted at the end of the procedure and the external component subsequently capped to facilitate internal drainage.

Results of balloon dilation

Balloon dilation alone has moderate success rates in treating ureteral obstruction, but generally requires repeat dilations. Initial reports employing balloon dilation of ureteral strictures suggested that outcomes were better when the strictures were anastomotic (i.e. postreconstructive procedure) and short in length [14–16]. More recent review of the literature suggests that the success rates of balloon dilation of ureteral strictures is noted in approximately 50% of all who present with ureteral obstruction, where results were best in patients with iatrogenic, nonanastomotic strictures, such as those following endoscopic instrumentation [17]. Ravery *et al*. found a 40% success rate using retrograde balloon dilation for inflammatory strictures at a mean follow-up of 16 months [18]. In a series of 114 patients with a minimum of 2-year follow-up, Richter *et al*. found higher success rates with balloon dilation for patients with relatively short ureteral strictures [19]. The authors also noted the significance of an intact vascular supply on success rates of balloon dilation. For longer ureteral strictures or those associated with compromised blood supply, the authors recommended performing an endoureterotomy as an alternative to balloon dilation, given the higher success rates with an incisional approach [19]. Interestingly, in experimental models, Nakada *et al*. demonstrated longitudinal incisions created by balloon dilation that were similar to those seen with formal endoureterotomy, possibly explaining the success seen with balloon dilation in managing some ureteral strictures [20].

Endoureterotomy

An endoureterotomy refers to a longitudinal endoluminal incision of the ureter and is a logical extension of balloon dilation for minimally invasive management of ureteral stricture disease. Similar to balloon dilation,

access across the strictured segment of ureter is required and this can be obtained either in a retrograde or an antegrade fashion. Retrograde access is usually preferred since it is less invasive. An endoureterotomy is preferably performed under direct vision using a ureteroscope rather than fluoroscopically using the hot wire cutting balloon catheter, given the close proximity of the common iliac vessels. Postoperative follow-up using a combination of renal ultrasound, intravenous pyelography, and diuretic renography may be performed to detect most late failures [9].

Retrograde ureteroscopic approach

The procedure begins with a retrograde pyelogram to identify the location and length of the stricture. As described previously, access is obtained across the strictured segment using either a floppy-tipped guidewire or hydrophilic glidewire. If passage of a wire is unsuccessful under fluoroscopic control alone, a flexible or semi-rigid ureteroscope can be advanced to the level of obstruction and an attempt at passing a wire through the ureteroscope under direct vision can be performed. The ureteroscope is then withdrawn, leaving the wire in place as a safety wire. The ureteroscope is then advanced beside the wire to the level of the stricture.

Prior to performing the endoureterotomy, it is critical to be aware of the blood supply to the particular segment of ureter that is involved. The direction of the endoureterotomy incision depends on the level of the ureter that is strictured. In general, lower ureteral strictures are incised in an anteromedial direction to avoid the iliac vessels. Upper ureteral strictures are incised laterally or posterolaterally, thereby avoiding the great vessels [21]. As mentioned previously, endoluminal ultrasound has been described to obtain realtime imaging of the surrounding periureteral vasculature to minimize the risk of bleeding at the time of endoureterotomy [22].

The endoureterotomy incision can be performed using a cold knife, a cutting electrode, or a holmium laser [23–25]. Regardless of the method chosen, the incision is made from the ureteral lumen out to periureteral fat in a full-thickness fashion. The endoureterotomy incision is continued proximally and distally to encompass 2–3 mm of normal ureteral tissue. Commonly the ureteral segment is balloon dilated post incision to help verify completion. Once the endoureterotomy incision is completed, an internal stent is placed over the safety wire. Larger diameter stents (10–14F) are preferred because they have been associated with improved results [9, 26]. Wolf *et al*. also found benefit in the injection of triamcinolone ureteroscopically after endoureterotomy. Thus, corticosteroids and other biologic response modifiers may have a role in the future in managing select strictures [9].

Reported results for ureteroscopic endoureterotomy using the cold knife, electrocautery, or holmium laser have been described in the literature. Eshghi and Lifson reported their results of cold-knife endoureterotomy in 89 patients with an overall success rate of 95% for initial treatment and 98% for repeat procedures [27]. In their study, no complications were encountered using this technique. Franco *et al.* reported a 100% success rate using cold-knife endoureterotomy in six patients with ureteral strictures, but with short follow-up of 3–8 months [28]. Yamada *et al*. treated 19 patients with a mean follow-up of 18 months and found an 85% success rate with cold-knife incision [24]. In a review of 36 ureteral strictures treated with endoureterotomy using electrocautery, Thomas reported a 64% success rate, with better results in patients with strictures less than 1.5 cm in length (80% success rate) compared with longer strictures (27% success rate) [29]. Previous radiation treatment also reduced success rates to 33%. In their review of electrocautery incisional treatment of ureteral strictures, most of which were secondary to schistosomiasis, Ghoneim *et al*. were successful in four of 12 patients [30]. Singal *et al*. reported a success rate of 76% using the holmium:YAG laser for endoureterotomy, with five of their 21 patients failing treatment [31].

Cautery wire balloon incision

Cautery wire balloon incision was reported by Chandhoke *et al*. in 1993 for the treatment of ureteropelvic junction obstruction and ureteral strictures [32]. This catheter was developed to simplify endopyelotomy and address the concern of ureteral stricture formation following retrograde endopyelotomy when larger diameter rigid ureteroscopes were used in the past [33]. As previously described, when performing this procedure, having safety wire access across the strictured segment is necessary prior to making the incision under fluoroscopic control. The cautery wire balloon can be inserted either in a retrograde or antegrade fashion and positioned appropriately using the radio-opaque markers. Again, the choice of location of the incision depends on the segment of ureter involved in order to avoid the blood supply to the ureter. The incision should be posterolateral in the proximal ureter and anteromedial in the distal ureter. Cautery wire balloon incision under fluoroscopy is not recommended in the mid ureter given the close proximity of the common iliac vessels to the ureter at this location. Success rates utilizing this technique have been described in the literature and, similar to other endourologic techniques, length and vascularity of the involved segment are critical factors in determining success rates [9, 33, 34]. Preminger *et al*. conducted a multicenter trial evaluating 49 patients and reported a 55% patency rate with a follow-up of 8.7

months [35]. With the advances in the design and miniaturization of current ureteroscopes, which have resulted in a reduction in ureteral stricture rates, cautery wire balloon incision under fluoroscopic control has largely fallen out of favor.

Antegrade approach

If the retrograde approach under direct vision is unsuccessful, an antegrade approach may be employed. Nephrostomy tube drainage is established and any infection or renal insufficiency allowed to resolve prior to proceeding with definitive incision of the ureteral stricture. The percutaneous tract is dilated to a size large enough to allow a working sheath through which a flexible ureteroscope may be passed. The procedure is then performed in an analogous fashion to that described for the retrograde approach.

Combined retrograde/antegrade approach

In rare situations, a ureteral stricture is associated with complete ureteral obstruction through which a guidewire cannot be passed in either a retrograde or antegrade fashion, thereby preventing balloon dilation or ureteroscopic endoureterotomy. A combined retrograde/antegrade approach has been described to manage such cases [25, 36–38]. Simultaneous retrograde and antegrade pyelogram is performed to identify the obstructed ureteral segment radiographically (Figure 43.4A). Ureteroscopes are then advanced both in an antegrade and retrograde fashion simultaneously to the obstructed segment (Figure 43.4C). This is confirmed fluoroscopically and the two ureteroscope ends are placed in line with one another (Figure 43.4D). A guidewire is then passed through one ureteral end, through-and-through to the other lumen, using a combination of fluoroscopy and direct visual control. If this is unsuccessful, a “cut-to-the-light” technique can be employed, whereby the ureteral segments are aligned as closely as possible using fluoroscopic and endoscopic control. The light source of one of the ureteroscopes is turned off and, using the light source of the other ureteroscope as a guide, an incision is made to restore ureteral continuity. A guidewire is then passed across the area incised to obtain through-and-through access (Fig. 43.4E). A stent is then inserted and left in place for 8–10 weeks to allow the area to heal. Endoscopy should be performed at the time of stent removal to re-evaluate the strictured area and determine if further endourologic maneuvers are required. Regular follow-up should be performed using a combination of renal ultrasound, intravenous urography, or nuclear renography to evaluate for stricture recurrence.

Success rates of combined retrograde/antegrade approaches, similar to other endourologic interventions, are inversely related to the length of the stricture. Knowles *et al*. reported a 90% patency rate in 10 patients who were treated for obliterated distal ureteral segments at 36 months of follow-up, of whom three required the combined approach [38].

Laparoscopic surgical repair

Prior to surgical repair of a ureteral stricture, it is important to conduct an evaluation of the nature, location, and length of the involved segment of ureter. This can be accomplished by performing a contrast imaging study: intravenous urogram, antegrade nephrostogram, or retrograde pyelogram, depending on the clinical circumstances. Ancillary studies, such as nuclear renography to assess renal function and ureteroscopy to define tissue viability and to help rule out upper tract carcinoma, should be performed depending on the clinical situation. Intraluminal sonography has an adjunctive role and has been employed to define the nature of a ureteral stricture including submucosal calculi, as well as periureteral structures including directly adjacent vasculature [10, 22]. Based on the results of these investigations, appropriate surgical intervention can then be planned and implemented.

Laparoscopic ureterolysis

Retroperitoneal fibrosis and certain gynecologic lesions (e.g. endometriosis) are among the more common benign conditions associated with extrinsic obstruction of the ureter. Ureterolysis is effective for correction of ureteral obstruction in 90% of patients with retroperitoneal fibrosis [39]. When open surgical intervention is employed, it may be associated with significant morbidity in up to 60% of cases [39]. With the development of laparoscopic techniques for ureterolysis, the morbidity of the procedure has been reduced. Elashry *et al*. compared six patients undergoing unilateral laparoscopic ureterolysis for extrinsic ureteral obstruction to seven undergoing open unilateral ureterolysis for similar pathologic conditions [39]. Laparoscopic ureterolysis was associated with less intraoperative blood loss and need for parenteral pain medication, and significantly shorter hospital stay and convalescence than open surgery. Operative time was only marginally longer in the laparoscopy group (255 vs 232 min). Excretory urography and/or renal scan showed improved renal function and relief of obstruction in all patients in this study.

Laparoscopic ureterolysis often begins with cystoscopic placement of a ureteral stent. The patient is then placed in the lateral decubitus position, pneumoperitoneum is obtained, and the laparoscopic ports are placed.

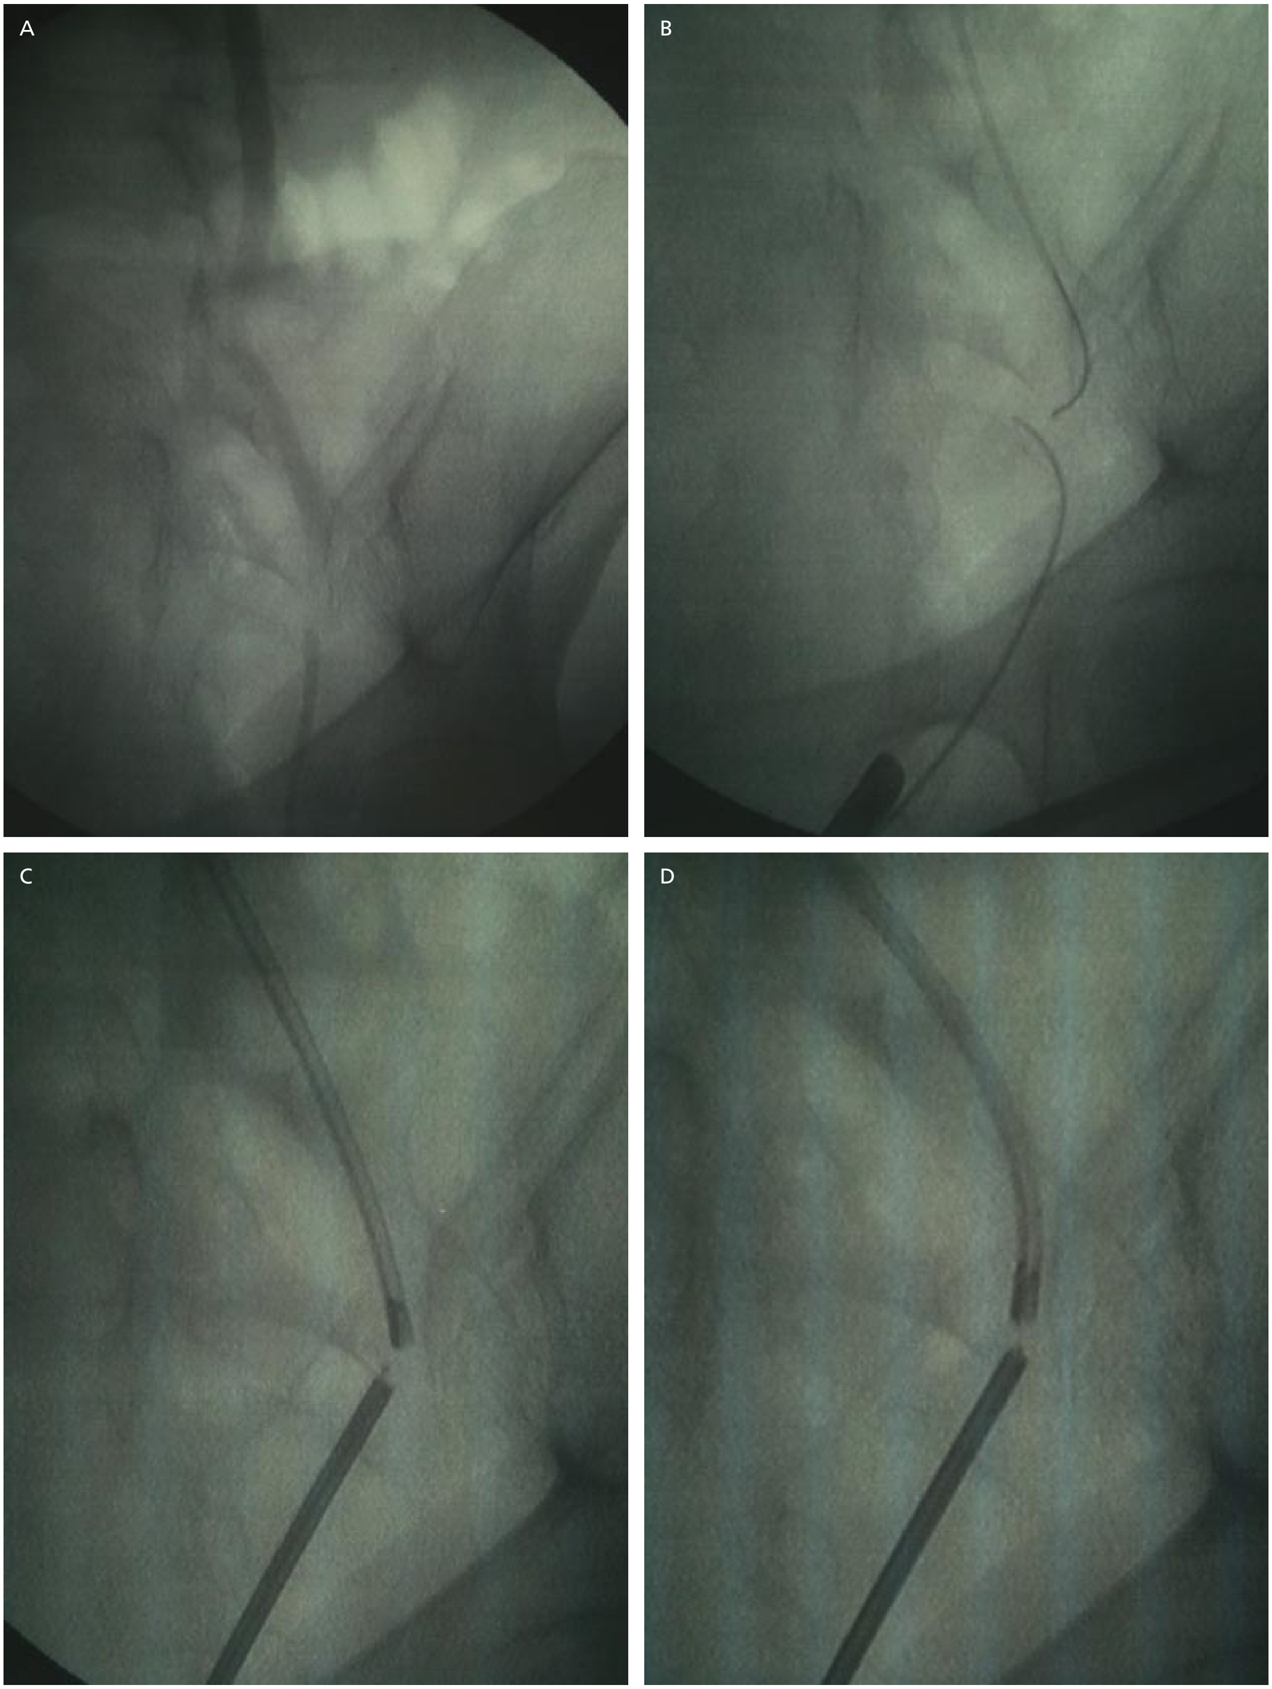

Figure 43.4 (A) Simultaneous antegrade and retrograde pyelogram defines a 1-cm obliterated ureteral segment. (B) Antegrade and retrograde attempts at obtaining guidewire access across the strictured segment under fluoroscopic control proved unsuccessful. (C) Simultaneous antegrade and retrograde ureteroscopy is performed. (D) The two ends of the ureteroscopes are lined up under fluoroscopic guidance and a "cut-to-the-light" technique is employed. (E) Access across the strictured segment is obtained in a retrograde fashion with a guidewire following the "cut-to-the-light" technique, which re-establishes ureteral continuity.

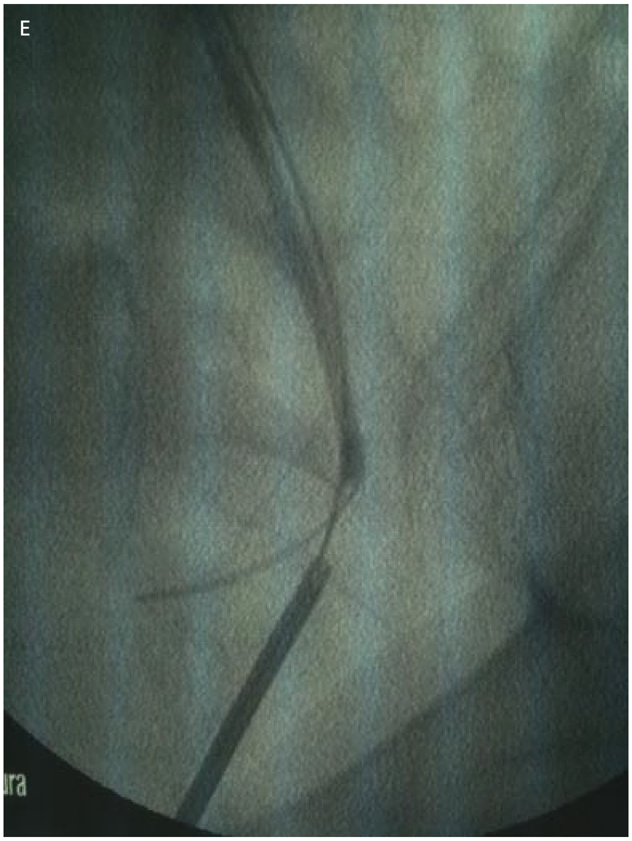

Figure 43.4 *Continued*

For mid-ureteral involvement, using four or five port sites has been described: a 12-mm umbilical or paraumbilical port, 5-mm subcostal upper midclavicular line port, 12-mm lower midclavicular line port below the umbilicus, 12-mm port off the 12th rib along the upper anterior axillary line, and 12-mm port at the umbilicus along the lower portion of the anterior axillary line [39].

The peritoneum is incised along the line of Toldt and extended caudally over the iliac vessels and medial to the medial umbilical ligament. The colon is reflected medially and the entrapped ureter identified with the indwelling stent acting as a guide. Meticulous dissection is performed to mobilize the ureter, freeing it from adjacent structures. Similar to the open surgical technique, a vessel loop can be placed around the ureter to facilitate gentle traction during mobilization. Dissection is carried out proximally and distally to healthy nonfibrotic tissue. A biopsy of the retroperitoneal fibrotic process can be helpful if clinically indicated. Once the ureter is freed from the retroperitoneal fibrotic process, it is positioned into the peritoneal cavity by reapproximating the previously incised edges of the posterior peritoneum using standard laparoscopic intracorporeal suturing techniques with 2-0 absorbable suture. Care should be taken to avoid iatrogenic ureteral obstruction or angulation. Placing an omental wrap is helpful, but is optional, and is based in part on the quality of this structure and the extent of intraperitoneal adhesions. Postoperative follow-up should include early imaging, at which time the ureteral stent can be removed. Serial imaging postoperatively should be performed to ensure long-term patency.

Laparoscopic ureteroureterostomy and ureterocalicostomy

Ureteroureterostomy is most appropriate for short strictures involving either the upper or mid ureter. Only short defects should be managed by end-to-end ureterostomy, as longer strictured segments may result in tension on the anastomosis with potential recurrence of obstruction. Determination of whether enough ureteral mobility can be achieved to obtain a tension-free ureteroureterostomy anastomosis is often an intraoperative decision. Long-term success with a tension-free, watertight ureteroureterostomy is well over 90% [40].

Ureteroureterostomy has been performed using both an open or laparoscopic approach. The laparoscopic technique, albeit endoscopic, follows the tenets of open surgical repair, creating a tension-free spatulated anastomosis. Nezhat *et al*. first reported laparoscopic management of an obstructed ureter secondary to ureteral endometriosis [41]. The obstructed ureteral segment was resected and the ureteroureterostomy was performed laparoscopically over a ureteral stent. In a retrospective review involving eight laparoscopic ureteroureterostomy patients, Nezhat *et al*. found seven patients to have a patent anastomosis, although follow-up was relatively short, ranging from 2–6 months [42]. Laparoscopic ureteroureterostomy is also an option for managing mid-ureteral obstruction due to a retrocaval ureter. Matsuda *et al*. performed this procedure using interrupted 4-0 polyglactin sutures over a stent after resecting a 3-cm fibrotic retrocaval ureteral segment [43]. Furthermore, Polascik and Chen have reported a case of laparoscopic ureteroureterostomy for retrocaval ureter using the EndoStitch (US Surgical, Norwalk, CT, USA) suturing device [44]. Operative times were 7.5 and 3.7 h, and hospital stays were 1 and 2 days in these two cases, respectively.

Laparoscopic management of ureteral injuries employing a primary ureteroureterostomy has also been described, albeit in only a few cases. When a ureteral injury occurs during a laparoscopic procedure, for example, it can be primarily repaired over a stent using intracorporeal laparoscopic suturing without the need for open conversion. Tulikangas *et al*. described four cases of distal ureteral injuries during gynecologic procedures [45]. Laparoscopic ureteroureterostomy with intracorporeal interrupted sutures was performed over

a ureteral stent. At a mean follow-up of 13 months (range 6–33), all four renal units showed no evidence of obstruction and no patient required repeat surgery. The overall clinical experience in laparoscopic ureteroureterostomy is broadening [46].

Ureterocalicostomy is a standard intervention for more proximal ureteral strictures that cannot be repaired with a primary ureteral reconstruction. As with ureteroureterostomy, laparoscopic technique should mirror the open surgical procedure. Laparoscopic renal mobilization is helpful. Resecting a generous portion of lower pole parenchyma and exposing a suitable calyx for anastomosis is key. Viable proximal ureter is spatulated and anastomosis performed with interrupted absorbable suture, commonly over a ureteral stent. Postoperative management and follow-up is identical to that employed with pyeloplasty. Both ureteroureterostomy and ureterocalicostomy reflect excellent minimally invasive interventions for moderate length ureteral strictures or injuries.

Laparoscopic Boari flap

When the diseased ureteral segment is distal and deemed too long for primary repair or when ureteral mobility is too limited to perform a tension-free ureteroureterostomy or a Psoas hitch ureteroneocystostomy, a Boari flap repair is a useful alternative. A Boari flap can be constructed to bridge up to a 15-cm long ureteral defect. Evaluation of bladder function should be performed preoperatively in addition to the aforementioned evaluation of the ureteral stricture. If there is evidence of bladder outlet obstruction or neurogenic dysfunction, this should be evaluated and addressed preoperatively. Additionally, the bladder should be of sufficient capacity to allow for creation of a sufficiently long Boari flap; otherwise alternative options should be considered.

A laparoscopic Boari flap has been successfully employed to treat long distal ureteral defects and strictures. Kavoussi *et al*. reported three successful cases where Boari flaps were used in the transperitoneal the management of distal ureteral obstruction [47]. Following open surgical principles, the bladder is mobilized from its peritoneal attachments and the most superior contralateral bladder pedicle is divided, allowing greater mobility toward the ipsilateral ureter. The ipsilateral bladder pedicle, including the superior vesical vasculature, is preserved and the affected ureter is carefully mobilized, with care taken to preserve its blood supply. Once the viable proximal ureter is defined, a posterolateral bladder flap is outlined based on the vascular supply of the ipsilateral superior vesical artery. The bladder flap is created and anastomosed to the spatulated ureteral end over a stent in a tension-free, watertight manner. Follow-up is based on serial evaluations, identical to the algorithm employed after open surgical repair.

In the report by Fugita *et al*., operative time ranged from 120 to 330 min, and blood loss ranged from 400 to 600 mL [47]. Two patients were discharged home within 3 days postoperatively, whereas one patient had a lengthy hospital stay due to *Clostridium difficile* colitis. Patency of the anastomosis was radiographically demonstrated at 6-month follow-up.

Conclusions

With advances in technique and endoscopic instrumentation, urologists are commonly employing minimally invasive therapies to address various urologic disorders, including ureteral obstruction. As progress continues in the field of endourology and laparoscopy, additional urologic procedures will be performed using a minimally invasive approach, reducing patient morbidity, while maintaining or expanding treatment efficacy. In this era of the endoscopist, minimally invasive treatment of ureteral strictures has not only become standard at teaching centers, but is also commonly employed in community settings worldwide.

CHAPTER 44
Distal Ureteral Strictures

Amin S. Herati[1] & Mohamed A. Atalla[2]

[1]The Smith Institute for Urology, Hofstra North Shore–LIJ School of Medicine at Hofstra University, New Hyde Park, NY, USA

[2]Department of Urology, Mid-Atlantic Permanente Medical Group, Largo, MD, USA

Introduction

Disorders of the distal ureter are common encounters for most urologists. Strictures are the second most commonly treated disorder, superseded only by obstructing ureteral calculi. Distal ureteral strictures can be defined as an abnormal narrowing involving the lower third of the ureter. Luminal obstruction can be partial or complete, with varying resultant effect. Most strictures pose clinical significance when they impair the ureter's principal function of expeditious forward transport of urine. Such an effect can result in pain, infection, calculus formation, or renal dysfunction. It is the latter sequela that mostly critically beckon the need for accurate and reliable diagnosis, and effective and durable treatment.

Strictures have historically been managed with open repair. However, advances in ureteroscope design, technique, and experience have reduced the morbidity and mortality associated with endoscopic repair. The apparent increase in incidence of clinically significant distal ureteral strictures paralleling the increased diversity in treatment options may not be a coincidence. This can be partly explained by the iatrogenic nature of a large proportion of strictures diagnosed today. Endoscopic management of upper tract calculi and other disorders has evidently come at a cost.

This chapter reviews the causes, diagnosis, and endoscopic management of distal ureteral strictures.

History

Endoscopic repair of ureteral strictures draws its origins from the late 19th century and early 20th century with reports of mechanical ureteral stricture dilation by Palwick in 1891 and balloon dilation in the management of ureteral stones by Dourmashkin in 1926 [1, 2]. Over the next five decades, instrument development allowed for smaller caliber endoscopes with the incorporation of dilating and cauterizing instruments. Interest in the endoscopic treatment of ureteral strictures re-emerged, first with balloon dilation in the early 1980s [3, 4] followed by cold-knife incision [5] and electrocautery [6], as well as laser in 1997 [7].

Etiology

The choice of treatment option often depends on the cause of a stricture, making it worthwhile to be familiar with the mechanism of each cause. Distal ureteral strictures can result from intrinsic or extrinsic causes, benign or malignant (Table 44.1). A variety of intrinsic and extrinsic factors often elicit an inflammatory cascade, resulting in disordered deposition of collagen bundles and smooth muscle.

Iatrogenic ureteral injuries account for a large number of the benign causes and are more likely to occur during gynecologic surgery, accounting for 52–82% of all operative injuries to the ureter [8]. Risk factors for ureteral injury during gynecologic surgery include uterine size, pelvic organ prolapse, and prior pelvic surgery. The ureter is most likely to be injured at the crossing of the uterine artery [9, 10]. Urologic procedures contribute a fair share of iatrogenic ureteral injuries that can lead to subsequent strictures. The incidence of iatrogenic injury during ureteroscopy at one point was as high as 10%,

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Table 44.1 Etiology of distal ureteral strictures.

Intrinsic

Benign

- Iatrogenic structure:
  - Hysterectomy
  - Ureteroscopy
  - Transurethral resection of the prostate
  - Extracorporeal shock-wave lithotripsy
  - Percutaneous nephrolithotomy
- Inflammatory disorders:
  - Amyloidosis
  - Sarcoidosis
  - Inflammatory bowel disease
  - Henoch-Schönlein purpura
- Radiation fibrosis
- Congenital abnormalities
- Ischemia
- Impacted stones

Malignant

- Transitional cell carcinoma of the ureter
- Metastasis

Extrinsic

Benign

- Periureteral fibrosis:
  - Abdominal aortic aneurysm
- Endometriosis
- Infectious etiology:
  - Tuberculosis
  - Schistosomiasis
- Retroperitoneal fibrosis

Malignant

- Cervical cancer
- Prostate cancer
- Uterine cancer
- Ovarian cancer
- Colon cancer

Figure 44.1 Distal ureteral stricture from tuberculosis.

but refinement in instrumentation and adoption of ureteral orifice dilation has reduced the stricture rate to less than 1% [11, 12]. Spontaneous passage of large stones or the passage of fragmented stones following extracorporeal shock-wave lithotripsy (ESWL) and percutaneous lithotomy (PCNL) procedures have also been linked to stricture formation [13–15]. In a retrospective review of 21 patients with a mean duration of stone impaction of 8.8 months, Roberts *et al*. found a statistically significant increase in stricture formation rates after 2 months of impaction [16]. Strictures can also result from bladder tumor resection in or around the ureteral orifice.

Benign conditions of the distal ureter that can result in strictures include ischemic, infectious, inflammatory, and congenital conditions. Ischemic conditions predispose the ureter to stricture formation, which is a recognized late complication in up to 10% of transplant nephrectomy [17, 18] and extrinsic compression by abdominal aortic aneurysms [19]. Infectious etiologies include tuberculosis [20] (Figure 44.1) and schistosomiasis [21], both of which have a constantly shifting demographic and geographic distribution. A number of inflammatory conditions can cause distal ureteral strictures, including endometriosis [22], sarcoidosis [23], amyloidosis [24], Henoch–Schönlein purpura [25], inflammatory bowel disease [26], and retroperitoneal fibrosis [27].

Malignant causes of distal strictures can mimic benign causes and must be ruled out when managing distal strictures. Causes of malignant obstruction can be of primary or metastatic origin and include transitional cell carcinoma of the ureter and metastases from the colon, cervix, prostate, bladder, or uterus. An important consideration in treating pelvic malignancies is the potential for stricture formation following pelvic irradiation.

Diagnosis

A detailed clinical history often reveals clues to the etiology of distal ureteral strictures. Symptoms of distal ureteral obstruction may include nausea, vomiting, flank

pain, hematuria, and symptoms of upper or lower tract urinary tract infection. Worsening symptoms during diuresis or polyuria should raise the suspicion of the astute clinician. Depending on baseline renal function, signs of renal insufficiency can also herald the diagnosis of distal ureteral stricture-related obstruction. However, distal strictures are asymptomatic in 25% of patients with diagnosis made upon incidental imaging or during attempted ureteroscopy [28]. When evaluating suspected strictures, basic laboratory investigation should include a urine analysis, urine culture, serum creatinine, and coagulation studies to determine the prothrombin time, partial thromboplastin time, and platelet count.

The first imaging test that will often lead the clinician towards a diagnosis is renal ultrasonography to detect hydroureteronephrosis. Ultrasonography is noninvasive and radiation free, making it an appropriate highly sensitive screening test. The modality is rarely able to identify the location, extent or cause of a stricture, though, and thus usually requires an additional study to establish a diagnosis. Excretory urography or multidetector computed tomography (MDCT) urography can better characterize a distal ureteral stricture. CT urography, particularly with three-dimensional and coronal reconstruction, provides detailed anatomic depictions of the distal ureter and adjacent extraluminal structures by collimating submillimeter-thick scan slices. Limitations of CT urography include its potentially harmful ionizing radiation and the risks of intravenous contrast administration [29].

Multidetector magnetic resonance (MR) urography is a reasonable alternative to CT urography, as it provides similar cross-sectional imaging without the harmful ionizing radiation. Moreover, a reduced dose of gadolinium-based contrast can be considered for patients with renal insufficiency. MR urography is not without its limitations, including its inferior spatial resolution compared to CT urography [30]. MR imaging also is not possible in patients with some metallic implants.

When possible, retrograde ureteropyelography has the advantage of potentially being performed concurrently with planned treatment (Figure 44.2). In addition, it allows avoidance of intravenous contrast and boasts low levels of radiation exposure. However, it provides little information on extraluminal disease processes, and is not always possible if the obstruction is severe or involves the ureteral orifice. When retrograde imaging is not possible, antegrade imaging via percutaneous renal access provides excellent anatomic delineation of a distal ureteral stricture without intravenous contrast (Figure 44.3). The same access can be also used to perform a pressure-flow study (the Whitaker test) to quantify the degree of ureteral obstruction. Antegrade imaging is the most invasive option, however, and carries risks of bleeding and adjacent organ injury.

Figure 44.2 Retrograde ureterography demonstrating a distal ureteral stricture.

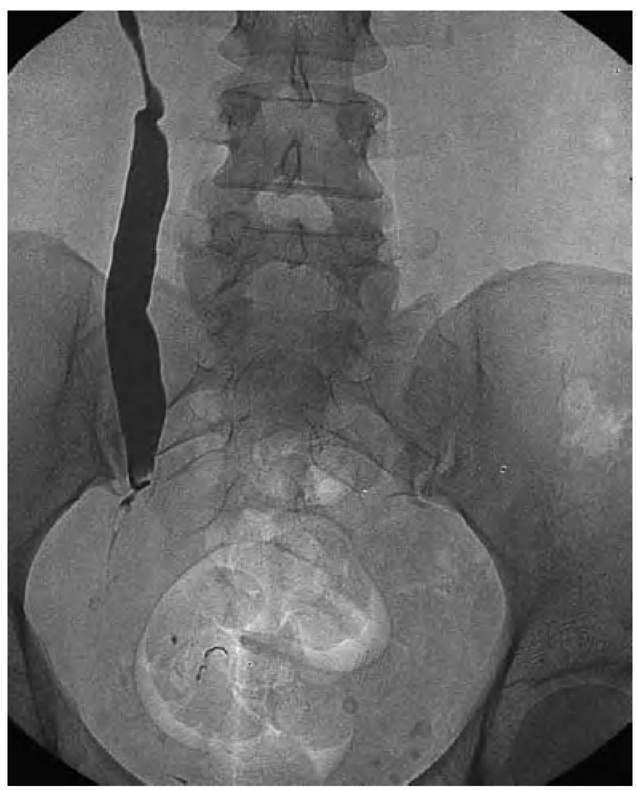

Figure 44.3 Antegrade ureterography demonstrating complete distal ureteral obstruction.

To quantify obstruction in a noninvasive manner, renal scintigraphy with diuretic washout provides the most accurate assessment [31]. Renal scintigraphy also allows the assessment of differential renal function, which may help guide treatment options. A renal unit contributing less than 15% of total renal function is associated with poor outcomes. If renal function is less than 25% on the ipsilateral side, observation alone is a reasonable option [32]. Temporary drainage with a percutaneous nephrostomy may be entertained and equivocal function reassessed after 4–6 weeks with renal scintigraphy, prior to definitive therapy.

Endoluminal ultrasonography has been a promising technique in assessing ureteral strictures. While it has fallen out of favor somewhat, endoluminal ultrasonography can provide useful anatomic detail of a stricture, including stricture length, the presence of extraluminal vascularity, and the extent of periureteral scarring and fibrosis. With experience, this modality can identify potential causes or associated conditions, such as ureteral endometriosis, retroperitoneal fibrosis, and surgical clips and staples [33]. Ultrasonography requires the ureteral caliber to allow the passage of a 6F probe and requires transurethral introduction via cystoscopy. A smaller 3.5F probe is available and may be passed through the working channel of some ureteroscopes. It is, therefore, only useful in partially obstructing distal ureteral strictures.

Preoperative preparation

Prior to intervention, all urinary tract infections should be treated and confirmation of treatment established with documentation of sterile urine preoperatively. Prophylactic preoperative antibiotics are indicated in all patients and can be given as single-dose therapy or continued for one to two doses after the procedure [34, 35]. Any suspicion of coagulopathy should prompt evaluation with appropriate testing and should be corrected preoperatively.

The patient is typically positioned in a dorsal lithotomy position for retrograde ureteroscopic approaches. If concurrent antegrade access is probable, the patient is placed in a prone split-leg position [36]. However, as comfort with supine percutaneous renal access increases, combined antegrade and retrograde approaches may be performed in a dorsal lithotomy position with the ipsilateral flank raised. Retrograde or antegrade ureterography under fluoroscopy is performed concurrently with treatment to map treatment. Access is achieved under fluoroscopy by passage of the surgeon's guidewire of choice. Initial access with an angled hydrophilic floppy-tipped guidewire may be needed to traverse some strictures.

Treatment options

Temporary relief of obstruction resulting from ureteral strictures is often achieved using ureteral stents or percutaneous nephrostomy. Patients with refractory strictures or who are not candidates for definitive treatment will often submit to long-term stent or nephrostomy exchange as a permanent solution. Stents for distal strictures resulting from extrinsic obstruction often are an unsuccessful long-term solution, with percutaneous drainage usually necessary after delayed stent failure [37]. Definitive treatment options for distal ureteral strictures include balloon dilation and ureteroscopic endoureterotomy.

Balloon dilation

Retrograde balloon dilation is often the first treatment attempted for distal ureteral strictures (Figure 44.4). Ureteral balloons vary in length (4–10 cm) and inflated diameter (4–10 mm), and can withstand maximum pressures of 40–225 pounds per square inch (psi). Using a porcine model, Clayman *et al*. demonstrated that the distal ureter can be safely dilated up to a caliber of 24F [38]. While perspectives differ on the optimal balloon size and technique, we prefer a 4-cm long, 6 mm (18F)

Figure 44.4 Balloon dilation of a distal ureteral stricture with "waisting."

balloon for most strictures. The success rate of retrograde balloon dilation for ureteral strictures has been estimated to be 48–88%, with a 10–29-month follow-up [1]. Predictors of durable success for balloon dilation include nonischemic strictures that are less than 1.5 cm in length and strictures that are less than 3 months old [39, 40]. In contrast, patients with ischemic strictures of longer lengths have demonstrable poor outcomes after balloon dilation with a patency rate of 16.7%.

Retrograde balloon endoureterotomy

The Acucise™ device (Applied Medical, Rancho Santa Margerita, CA, USA) incorporates a low-pressure ureteral balloon dilator with monopolar electrocautery for retrograde incisions under fluoroscopic guidance [41]. The balloon helps identify the diseased segment (as demonstrated by "waisting") and provides tamponade following cauterized incision. With only fluoroscopic guidance possible, careful patient and stricture selection is needed to help reduce hemorrhage risk. Additionally, the cutting wire should be oriented in an anteromedial position when incising the ureter distal to the iliac arteries, and should never be used at the level of iliac vessel crossing. For an incision to be effective, cutting should be extended through the full thickness of the ureteral wall until periureteral fat is visible or until an adequate luminal diameter has been established. Without direct visualization, this translates into contrast extrusion on a subsequent retrograde ureterogram. Incision also should extend at least 2 mm proximal and distal to the area of stricture, and not just until balloon waisting is lost.

Preminger *et al*. evaluated the efficacy of the Acucise device in 26 patients with distal strictures, and found 58% were patent and a further 15% improved after an average follow-up of 7.8 months [41]. Knowles *et al*. performed balloon endoureterotomy using the Acucise device for 10 strictures in nine patients with complete distal ureteral obstruction [42]. They used a mixture of approaches (retrograde, antegrade, and combined), and found 90% success with a durable median follow-up of 36 months. The use of endoluminal ultrasonography prior to balloon endoureterotomy using the Acucise device reduced associated complications in a study by Hendrikx *et al*. [43]. The group found no bleeding in a series of 27 patients following endoluminal ultrasonographic markings of periureteric structures.

Ureteroscopic endoureterotomy

A limitation of balloon endoureterotomy for ureteral strictures or ureteropelvic junction obstruction is the lack of direct visualization. Incision of strictures via ureteroscopy can be achieved using different modalities, including a cold knife, electrocautery, or holmium:YAG laser. Cold-knife incisions can be performed with straight, hook, or half-moon configured blades under direct vision via a rigid ureteroscope. Incisions are made under endoscopic visualization and always with guidewire access control (when not precluded by complete obstruction) [44]. Using a cold-knife incision has the advantage of a relatively low local inflammatory and cicatricial response because of the lack of energy transmitted [45]. Cold-knife endoureterotomy has overall high rates of success for primary and salvage procedures. The largest series to date of distal endoureterotomies performed with a cold knife was reported by Eshghi and Lifson, showing a 95% success rate for 100 strictures in 89 patients [28].

Electrocautery can be used to incise distal ureteral strictures via ureteroscopy using 2–3F ball-tip electrocautery probes. While electrocautery boasts better hemostasis than a cold knife, it results in a more substantial local tissue response, which carries a high stricture recurrence risk. Electrocautery requires the access guidewire to be a well-insulated wire, or alternatively a narrow ureteral catheter, to prevent longitudinal transmission of the current. A few studies have evaluated the efficacy of electrocautery in the distal ureter, including one by Ghoneim *et al*. demonstrating success in only two of 10 patients with distal ureteral strictures, with failures attributed to bilharzial and iatrogenic strictures [46].

Combining accuracy and reduced local response, laser endoureterotomy is associated with the most favorable results for distal ureteral strictures. Holmium:YAG lasers can be operated at 10 W (10 J at 10 Hz) with low-power generators and through 200-μm laser fibers that can pass through either semi-rigid or flexible ureteroscopes [1, 47]. Holmium:YAG lasers have the versatility of treating any associated calculi. Thirteen patients with stricture disease secondary to stone disease underwent laser endoureterotomy with a success rate of 56% [48]. In a large review of patients undergoing laser endoureterotomy with holmium:YAG, Lane *et al*. reported a success rate of 75% with a mean follow-up of 36 months, and found that failures were most likely within 3 months of treatment [49]. Despite the precision of laser endoureterotomy, Figenshau *et al*. found no significant difference in the histologic changes between balloon dilation, Acucise, and endoscopic incision with a cold knife, laser, or electrocautery in a porcine model [50]. Similarly, Wolf *et al.* found no difference between the cutting modalities in a multivariate analysis with an overall success of 80% at 3 years [32].

Ureteral stenting after treatment of distal strictures is generally not contested. Stent use theoretically prevents recurrent stricture formation and urine extravasation, and promotes healing [1]. The choice of stent type and size has been the subject of much debate, without defini-

tive data to support the superiority of one. We prefer the use of a 7F double pigtail stent, although two 6F stents or a gently tapered endoureterotomy stent (6/10F) are viable alternatives. We recommend stent use for 6 weeks after treatment of a stricture. Stricture recurrence should be ruled out between 6 and 12 weeks after stent removal with renal ultrasonography, CT urography, excretory urography, or diuretic renography. Asymptomatic patients with normal early postoperative imaging should be reimaged at 6-month intervals for up to 3 years, as strictures are most likely to recur within the first 3–36 months [32, 49, 51].

Challenging strictures

Ureteroenteric strictures

Ureteroenteric strictures are recognized late complications of 3–10% of urinary diversion procedures [52–54]. Ischemia is the most likely precipitating factor (Figure 44.5). Numerous endourologic techniques have been applied in the management of these complex strictures, including balloon dilation (Figure 44.6), balloon endoureterotomy, and ureteroscopic endoureterotomy. A combined antegrade and retrograde approach is often necessary due to the complexity of these strictures. In a review of 30 strictures in 25 patients by Wolf *et al*., the overall success rate for all endourologic procedures in the treatment of ureteroenteric strictures was estimated to be 72%, 51%, and 32% at 1-, 2-, and 3-year follow-up, respectively [32]. They also found that right-sided endoureterotomies had significantly better outcomes compared to left-sided endoureterotomies (68% vs 17%). This difference could be attributed to ischemia due to the more convoluted course of the left ureter posterior to the sigmoid colonic mesentery, and the higher likelihood of tension on the ureteroenteric anastomosis. Cold-knife endoureterotomy has been reported to have a 3-year success rate of 60.5%, closely followed by holmium:YAG endoureterotomy with a 56% patency rate at 3 years [55, 56]. Ureteroenteric strictures are discussed further in Chapter 45.

Renal transplantation strictures

Ureteral strictures following renal transplantation are associated with patient and graft morbidity, and can result in graft loss or death. Stricture rates are related to the reimplantation technique used. The highest rates of ureteral stricture have been observed with the Leadbetter–Politano anastomosis (12.4%) [57–60]. The majority of post-transplant strictures present distally and often involve the ureterovesical junction [61, 62].

Figure 44.5 Ureteroenteric stricture.

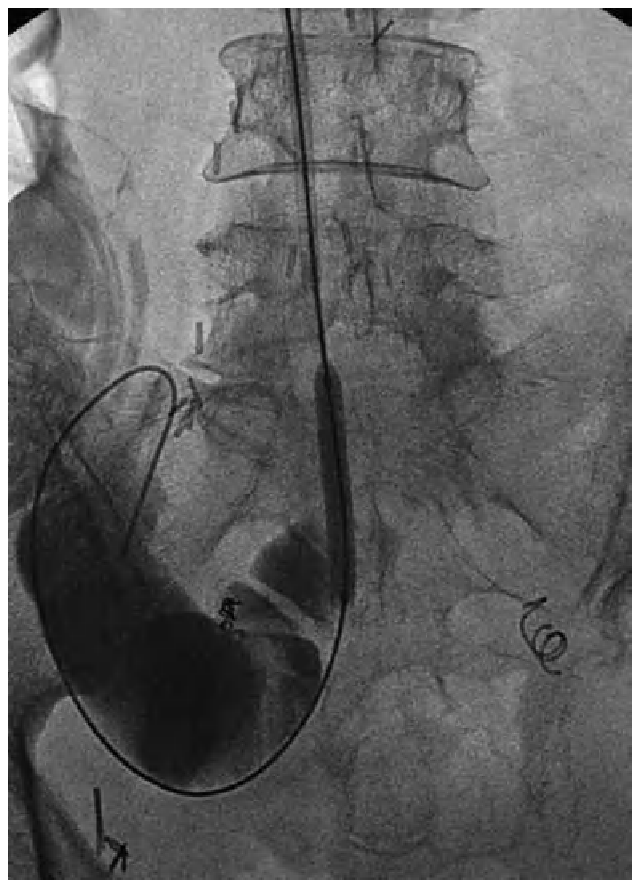

Figure 44.6 Balloon dilation of ureteroenteric stricture.

Retrograde or percutaneous ureteral balloon dilation is the initial method of choice in treating ureteral strictures and has been performed with varying success rates. Lojanapiwat *et al*. demonstrated a 71% success rate using antegrade balloon dilation for strictures that presented within 3 months of transplantation, in contrast to only 29% for strictures treated greater than 3 months after transplantation [62]. Bosma *et al*. treated 13 patients with a retrograde, antegrade, or combined approach, with dilation only in nine patients and dilation and electrocautery in four patients. After a mean follow-up of 58 months, four of the patients who underwent dilation alone developed recurrent obstruction [63].

Endoureterotomy techniques have also been used in the treatment of renal transplant strictures. Synergistic effects between antegrade balloon dilation and holmium:YAG endoureterotomy were seen in a study by Gdor *et al* [64]. The group showed success in four of six patients with a combined approach, compared with only one of three patients treated with balloon dilation alone. Conrad *et al*. evaluated cold-knife endoureterotomy for 11 transplant strictures and found 82% patency after 26 months of follow-up [65]. The Acucise device was successful in two of three patient with transplant strictures after a mean of 20 months [66].

Subtotal and total obstruction

Advances in technique and instrumentation have expanded the role of endoscopic approaches to include ureteral strictures causing complete or near complete obstruction. Bach *et al*. recently described their technique of blind retrograde endoureterotomy, which is performed under fluoroscopic control using either a holmium:YAG or thulium:YAG laser slowly pulled through the stenotic area [67]. However, 38.8% of patients developed recurrence of obstruction after a median follow-up of 1 year. To perform blind retrograde endoureterotomy, a glidewire and a 4F catheter must be passed through the stricture. Alternatively, passage of microwires and microcatheters can be attempted percutaneously in an antegrade fashion [68, 69].

For short complete obstructions less than 2 cm in length, endoscopic recanalization can be performed with a “cut-to-the-light” procedure [70]. This approach requires percutaneous access for a flexible ureteroscope to pass down the ureter. A semi-rigid ureteroscope is simultaneously passed up the distal ureter. The light transmitted from one endoscope guides the electrode or laser of the other endoscope. Recanalization was successful in a case series of three patients using the holmium:YAG laser [71]. Alternatively, the stiff end of a guidewire can be used to pierce the obstructing tissue with subsequent dilation. Using this technique, Colins *et al*. demonstrated a 100% recanalization rate and 75% long-term success in eight patients after a median follow-up of 87 months [72]. Similar results were obtained by Tsai *et al*., who combined ureteroscopy with a fluoroscopic-guided antegrade snare to re-establish ureteral continuity in 10 patients with a mean follow-up of 16 months [73].

Conclusions

Distal ureteral strictures are encountered by every urologist. The etiology, severity and extent, associated renal function, and adjacent pathology should dictate the approach for management. A tailored systematic algorithm should be planned for each patient, being mindful of success rates and complications. When endourologic management fails to achieve durable results, open and laparoscopic approaches should be considered.

CHAPTER 45

Endoscopic Management of Ureteroenteric Strictures

Davis P. Viprakasit & S. Duke Herrell

Vanderbilt University Medical Center, Department of Urologic Surgery, Nashville, TN, USA

Introduction

Ureteroenteric strictures following radical cystectomy and urinary diversion have a reported incidence of 4–8% [1, 2]. Following the diagnosis, management of these strictures represents a treatment dilemma. While open exploratory laparotomy and revision of the narrowed anastomosis is the gold standard treatment, with success rates of 89–91% [3, 4], surgical revision can be technically challenging secondary to dense fibrosis and adhesions associated with the prior surgery or radiotherapy. Advances in endourologic instruments and techniques have allowed many endoscopic procedures to be used in the primary management of ureteroenteric strictures. While long-term success rates have not been as robust as those for open treatment, these less invasive techniques uniformly offer shorter hospitalization, reduced blood loss, and quicker convalescence [5]. This decreased associated morbidity may be particularly beneficial in patients who would otherwise be poor surgical candidates. As the overall incidence of ureteroenteric strictures is relatively low, most studies describing the various endoscopic procedures are limited to small case series or single institution experiences, making overall evaluation difficult. However, some concerns exist for patients who fail endoscopic treatments. Contemporary reports of open revision suggest slightly lower long-term success rates (76–80%) than previously noted [6, 7]. Some authors hypothesize that this may be secondary to inclusion of more difficult patients who previously failed primary endoscopic management [7].

In this chapter, we review the endoscopic management techniques of ureteroenteric strictures and detail the outcomes of the various approaches in the literature identified by a PubMed and MEDLINE search in order to determine which patients could undergo endoscopic intervention and which should be offered open revision as first-line therapy.

Etiology and characteristics

Ureteroenteric strictures are most commonly classified as benign and ischemic in origin, and have been reported following all types of urinary diversions [8]. Malignant recurrence at the anastomosis is rare, with reported rates of 0–0.7% [9–11]. The etiology of ureteroenteric strictures is largely multifactorial. Several technical considerations at the time of radical cystectomy may promote stricture development. Inadequate ureteral length or extensive skeletonization of the periureteral microvasculature during ureteral mobilization and diversion creation may result in compromised blood supply to the distal ureter. The longer ureteral course to meet the bowel as well as misapproximation of the ureteroenteric anastomosis may promote ureteral angulation or torsion [12]. This likely reflects the predominance of left-sided strictures often observed secondary to the length and degree of mobilization required to tunnel the left ureter under the mesentery [13]. Additionally, inherent differences with the apposition of the two different mucosal types, as well as urinary exposure and autoimmune responses, may promote stricture formation [14, 15]. The

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

type of ureteroenteric anastomosis after urinary diversion may also relate to stricture occurrence. Despite an increased risk for bilateral renal obstruction, the conjoined end-to-end ureteral anastomosis (Wallace) has a lower reported stricture rate as compared with the individually implanted ureteral anastomosis (Bricker) [16, 17], though this has not been uniformly observed [18]. A direct refluxing anastomosis generally has a decreased stricture incidence compared to antirefluxing anastomoses [19], though some variability has also been reported [20]. Other factors that have been implicated in the development of ureteroenteric strictures include the use and type of ureteral stent at the time of diversion [21, 22], patient obesity [body mass index (BMI) >30 kg/m^2], and pelvic radiation therapy [16].

Diagnosis

Patients with ureteroenteric strictures may be symptomatic on presentation with unexplained flank pain, hematuria, or recurrent urinary tract infections (UTIs) [23, 24]. However, in other patients, the diagnosis is made on evaluation of increased serum creatinine or incidentally noted with the finding of hydronephrosis on imaging, which reiterates the importance of regular, routine follow-up (Figure 45.1). Initial radiographic studies typically include computed tomography (CT) or renal ultrasonography to evaluate for hydronephrosis. Additional functional imaging such as renal scintigraphy, excretory urography, antegrade nephrostography, or loopography/neobladder cystography should be performed in order to confirm the diagnosis and determine the stricture length and location (Figure 45.2). Reflux from urinary diversion should be excluded from the diagnosis as chronic reflux can cause hydronephrosis without obstruction. Urine cytology should be examined in all patients to rule out malignant recurrence. As many of these patients have undergone diversion secondary to a history of primary bladder or pelvic malignancy, a high index of suspicion for malignant obstruction should be maintained and appropriate cross-sectional imaging and endoscopic visualization to rule out malignant obstruction should always be undertaken prior to definitive stricture treatment. In patients with suspicious lesions, ureteral biopsies may be required for definitive diagnosis.

Indications for intervention

Early decompression is generally warranted in patients with ureteroenteric strictures. In patients with significant flank pain or concerning infection, prompt drainage can relieve symptoms or prevent impending sepsis. Asymptomatic patients with ureteroenteric stricture are at risk for developing worsening hydronephrosis and compromised renal function. These two factors, specifically an ipsilateral renal function of less than 25%, have been associated with poor outcomes following ureteroenteric stricture treatment [13]. Percutaneous nephrostomy is the most common and effective method for early decompression. This also allows for antegrade

Figure 45.1 Antegrade nephrostogram. Left ureteroenteric stricture in patient with Bricker-type ileal conduit resulting in hydroureteronephrosis.

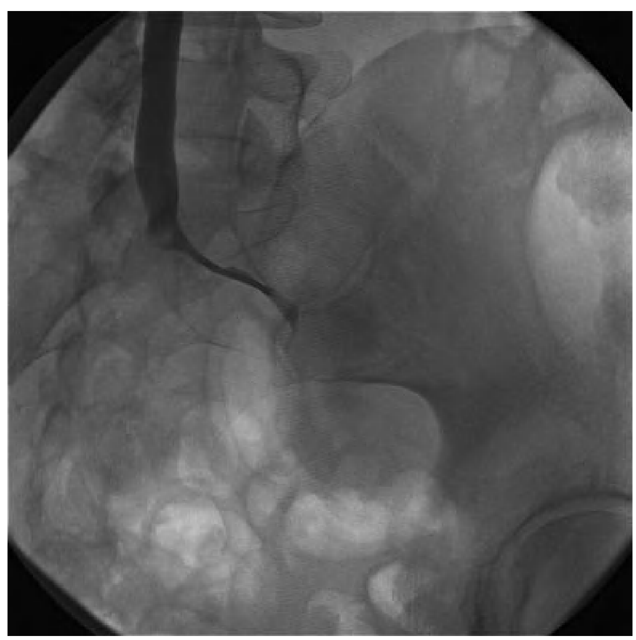

Figure 45.2 Antegrade ureterogram delineates ureteroenteric stricture.

diagnostic studies to be performed while awaiting renal function and infections to improve prior to definitive therapy.

Surgical techniques

Endoscopic management of ureteroenteric strictures can be performed using an antegrade, retrograde, or a combination of the two approaches. As we typically decompress patients with a percutaneous nephrostomy tube after the initial discovery of obstruction, we generally approach the stricture in an antegrade fashion. An angled-tip 0.038-inch hydrophilic nitinol core glidewire is advanced through the previously placed nephrostomy access and manipulated into the conduit or neobladder. A 5F Cobra-tipped angiographic catheter is used to help facilitate wire positioning into the ureter if necessary. The glidewire is next exchanged for an Amplatz super-stiff wire. A second standard guidewire is placed as a safety wire down the ureter following placement of an 8/10F coaxial dilator over the super-stiff wire. Depending on surgeon preference, a variety of types of tract dilatation and sheath placement are possible. For ureteral evaluation and treatment, we typically prefer placement of a smaller diameter 18F Amplatz sheath or a short 13 or 15F ureteral access sheath. Both flexible ureteroscopy and an antegrade nephrostogram are performed to characterize the location and degree of stenosis. Biopsies and washings for cytology should be taken to evaluate for recurrence in all cases of transitional cell carcinoma where suspicion is high for malignant obstruction. In patients with significant tortuosity and angulation of the ureter, an 11/13F x 36 cm ureteral access sheath is placed through the Amplatz sheath in order to negotiate to the distal ureter. Further individualized endoscopic management is detailed below.

Balloon dilation

Balloon dilation of the ureteroenteric stricture can be performed primarily or in conjunction with another endoscopic modality such as endoureterotomy. After manipulation of the guidewire past the area of stenosis, a UroMax Ultra Balloon catheter with an outer diameter of 15–18F at a length of 4 cm is placed in the narrowed region under fluoroscopic guidance. The balloon is inflated to approximately 12–15 atm until the narrowed waist is removed (Figure 45.3). After maintaining the dilation for 3–5 min, the balloon is deflated and removed. Flexible ureteroscopy is performed in order to inspect the strictured site. Repeated balloon dilation can be performed for any residual scar tissue. At the conclusion of the procedure, a stent is placed across the dilated segment (see Stenting options below).

Figure 45.3 Balloon dilation of distal left ureteroenteric stricture after cystectomy.

Endoureterotomy

Incision of the strictured ureteral segment can be performed using a variety of cutting sources [cold, hot (electrosurgical probes/Acucise™), holmium:YAG laser] either under direct vision or fluoroscopic guidance. In significantly narrowed ureters, initial balloon dilation may be required to allow complete access to the stricture. A full-thickness incision extending 1 cm beyond both ends of the strictured area is made through the ureter until periureteral fat is noted or contrast extravasation is observed under fluoroscopy [25]. Some investigators have advocated the adjunct use of triamcinolone steroid (3–5 mL at 40 mg/mL) injected endoscopically with a 3F Greenwald needle into the incised stricture bed for improved patency [13, 26]. After direct visual or fluoroscopic confirmation of the desired stricture release, a stent is placed. Detailed descriptions regarding each type of cutting device are listed below.

Cold knife

Cold-knife endoureterotomes are generally used with semi-rigid ureteroresectoscopes for retrograde incision of the stricture. The larger diameter sheath and lack of flexibility of the scope limits the extent of narrowing that can be treated under direct visualization. The stricture is cut using arc-like strokes until the ureteral lumen widens enough to allow passage of the scope. Small mucosal bleeding vessels are not routinely fulgurated to minimize the extent of potential thermal injury [27]. A flexible, wire-mounted cold-knife has been described that allows both antegrade and retrograde incision. The wire can be placed through the working channel of the scope to directly guide the blade through the shaft of the knife or pulled under fluoroscopic guidance. Several incisions may be required to fully release the fibrotic stricture [28].

Electrocautery

Under direct visualization, the smaller Greenwald 2 or 3F electrode probe can be utilized through the semi-rigid or flexible ureteroscope. At a power setting of 75 W on pure cutting electrocautery current, multiple incisions of the stricture are made using the probe until the fibrotic bands are released. The incision width and length can be fully controlled under direct visualization and hemostasis can be achieved if necessary. A variation of the technique has been described by Lovaco *et al*. that incorporates a dilation balloon pulled in a retrograde fashion to invaginate the stricture and allows subsequent intraluminal incision of the complete, well-exposed stricture using electrocautery [24]. Care must be taken to insulate any safety wires that might be exposed to electrical current to prevent conduction to other segments of the ureter or tract.

Acucise™ balloon catheter

The 7F Acucise cutting balloon catheter combines a monopolar electrocautery cutting wire and a 24F low-pressure balloon, and can be placed either in an anterograde or retrograde fashion. Though originally developed for treatment of ureteropelvic junction obstruction (UPJO), the device is approved by the Food and Drug Administration (FDA) for use throughout the ureter [29]. After direct visualization of the narrowed area, the Acucise catheter is advanced over the guidewire using fluoroscopic guidance with the radio-opaque markers at either end of the 3-cm active cutting surface positioned in the area of the ureteroenteric stricture. Attention is given to position the cutting wire in the posteromedial orientation after visual confirmation of an absence of any pulsations in the area of the proposed cut. The Acucise balloon is subsequently inflated with 2 mL of contrast along with simultaneous activation of the cutting wire at 75 W on pure cutting electrocautery current for 5 s. After maintaining the dilation for 3–5 min, the balloon is deflated. It can be repositioned to traverse any residual narrowing and reactivated as needed.

Laser

Ureteroenteric stricture incision is performed at the 6 o'clock position with the patient in the prone position, away from the iliac vessels. A 200-μn holmium:YAG laser fiber is placed through the flexible ureteroscope at a setting of 10 W (1 J and 10 Hz) and used to incise the fibrotic tissue under direct visualization until release of the scar tissue and periureteral fat is evident [30]. Contrast instillation through the endoureterotomy site may show a small amount of extravasation, confirming the adequacy of the incision. While other types of lasers (Nd:YAG, KTP Nd:YAG) can be used for stricture incision, the holmium:YAG is predominantly used because of its ablative and hemostatic properties [25]. With a depth of penetration of less than 0.5 mm, the laser allows for precise incision with a minimal peripheral zone of thermal injury (0.5–1 mm) [5].

Ureteral stenting

Most patients treated with balloon dilation or endoureterotomy additionally undergo ureteral stent placement at the conclusion of the procedure. The stent remains for a finite period of time in order to maintain ureteral patency, prevent urine extravasation, and promote healing. The optimal stent duration is unclear. Significantly prolonged stent duration, however, may promote hyperplastic tissue growth or scarring and prevent adequate healing [25]. Additionally, there is a lack of consensus regarding optimal stent size. Some authors advocate larger stents [13], though others believe that increased pressure from oversized stents may promote fibrosis and recurrent strictures [31]. The stent can be positioned either antegrade or retrograde after establishing guidewire access across the ureteroenteric stricture in a through-and-through fashion. Double-J stents are most commonly used but may be difficult to exchange in patients with incontinent diversions. In patients with an ileal conduit, a nephroureteral stent can be advanced over the exposed guidewire from the stoma in a retrograde fashion to the renal pelvis, with the external portion of the stent placed in the stoma bag for external drainage [32]. In patients who are too ill for more definitive therapy or it is their preference, chronic indwelling ureteral stents may be utilized as the primary treatment. All synthetic stents, however, require periodic exchange secondary to subsequent encrustation and obstruction. Double-J stent exchange is generally recommended every 3–6 months and typically requires an anesthetic in the operating room.

The use of metal ureteral stents for ureteroenteric strictures is controversial. Metallic stents have proven success in other organ systems but, in urology, have primarily been employed for malignant ureteral obstruction [33]. Full-length, double-pigtail metallic stents similar to synthetic double-J stents have the advantage of once-yearly exchanges. Initially, a metallic stent introducer is passed over the existing guidewire. After removal of the wire, the metallic stent is passed through the lumen of the introducer sheath. The sheath is subsequently removed, leaving the stent in place [34]. Short, permanent, balloon, or self-expandable metal stents, similar to vascular stents, have also been utilized for ureteroenteric strictures. They do not require exchange. These metallic stents are deployed using a manufacturer delivery system over the guidewire and positioned such

that 3–4 cm of the stent extends beyond the stricture proximally and 0.5–1 cm distally. Attention is given to ensure that less than 0.5 cm of the stent protrudes distally into the neobladder or ileal conduit lumen to minimize urinary contact. After fluoroscopic confirmation of proper positioning, the outer sheath of the delivery system is removed, thus releasing the stent. If necessary, two or more stents may be placed in tandem for longer strictures [33].

Retrograde approaches

While antegrade or combined antegrade/retrograde approaches are generally utilized in the management of ureteroenteric strictures, direct retrograde access can conversely be attempted to minimize the potential morbidity of percutaneous techniques. Initial retrograde access can be challenging secondary to inability to locate the ureteral orifice within the intestinal mucosal folds of the diversion or difficult location or angle of the ureteral orifice. Additionally, access to the orifice may be prohibited in patients with very long or tortuous diversion limbs. Identification of the ureteral orifice may be aided by the excretion of indigo carmine following intravenous administration [35]. Also, contrast instillation within the urinary diversion may allow for better delineation of the appropriate diversion limb and location of the ureteral anastomosis [36]. Retrograde access is generally not feasible in patients with nonrefluxing anastomoses secondary to the antireflux mechanism [37]. However, in other patients, once the ureteral orifice has been identified, a straight or angled-tip 0.038-inch hydrophilic nitinol core glidewire in combination with a 5F Cobra-tipped angiographic catheter can be used to help facilitate access into the ureter. Wire advancement through the obstructed segment may be difficult in patients with significant stenosis or long (>1 cm) strictures and require antegrade approaches. Following wire placement past the level of obstruction, any of the previously discussed endoscopic techniques may be utilized.

Surgical outcomes

While there is some variability in the literature, operative success was defined as radiographic improvement/resolution of obstruction and/or a recovery to normal activity without flank pain, infection or need for ureteral stent/nephrostomy tube [24, 28, 38].

Balloon dilation

In eleven publications describing 150 primary balloon dilations of ureteroenteric strictures in both continent and incontinent diversions, success was reported in 0–67% (mean 33%) of cases at a mean follow-up of 4–48 months (Table 45.1) [6, 12, 23, 39–46]. While initial results appeared favorable, later results have been less promising at longer follow-up. Review of the largest and more contemporary series shows patency rates of only 15% at a 1- and 2-year follow-up, which decreased to 5% at 3 years [6].There was no consensus regarding balloon size (4–10 mm), inflation time (30 s—10 min), number of inflation cycles (1–3), or inflation pressures (5–17 atm). Additionally, while most studies utilized stents at the conclusion of the procedure, a variety of stent sizes (5–24F) and duration of stenting (days to months) was reported. Although there were no uniform predictors of success and not every publication evaluated each parameter, some trends were observed. The side of the stricture and degree of stenosis did not influence outcomes. Longer strictures (>1–2 cm) were less likely to have long-term success. A shorter duration between urinary diversion and balloon dilation was a more likely predictor of success, though this was not uniform [6, 12, 23, 39–46].

The poor durable results of this technique may be explained by the physiologic effects of balloon dilation. Single-step, high-pressure balloons allow radial dilation of the stricture without the shearing trauma associated with serial stepwise catheter dilation [29]. However, as noted for UPJO, poor long-term results following balloon dilation of ureteroenteric strictures may occur because the epithelium and lamina propria are split without a corresponding split to the muscularis propria or adventitial layer [47, 48]. Additionally, hydraulic trauma to the neighboring healthy ureter may result in further ischemic damage [30].

Endoureterotomy

Incision of the strictured ureteral segment, whether by cold knife, electrocautery, electroincision or laser, is the current endoscopic standard [23]. The technique is based on animal studies by Davis in 1943 with intubated ureterotomy [49]. Davis noted that incised ureters healed over a stent by regrowth of the urothelium and subsequent smooth muscle within approximately 6 weeks. Ureteral patency was noted in 70% of incisions [50]. Later animal studies involving endoureterotomy noted that there were no significant difference in tissue injury, periureteral edema, and inflammation regardless of the cutting modality used [48].

In 17 studies involving 147 endoureterotomy procedures, overall success was reported in 30–100% (mean 66%) of cases at a mean follow-up of 10–60 months (Table 45.2) [3, 5, 13, 23, 24, 26, 28, 30, 38, 51–58].While the total numbers of procedures in each group were comparable, small procedure numbers in each individual case series make direct comparison between the
